The main biosynthetic pathway for catecholamines in mammals starts with *tyrosine* derived either from the diet or formed through hydroxylation of phenylalanine in the liver. Tyrosine is first converted to 1-dihydroxyphenylalanine (DOPA) by tyrosine hydroxylase, and DOPA is then decarboxylated to 1-dihydroxyphenylethylamine (DOPAmine) by l-amino acid decarboxylase, which subsequently undergoes β-hydroxylation (by DOPAmine β-hydroxylase) to *norepinephrine* (Fig. 3.89).

Though the adrenal medulla does not appear to be absolutely essential for life, there are a number of physiologic conditions (e.g., sudden hypoglycemia and acute stress) in which release of epinephrine from the medulla is beneficial. Stimulation by preganglionic sympathetic fibers that synapse on secretory cells of the adrenal medulla also increases the output of catecholamines, primarily by increasing tyrosine hydroxylase and DOPAmine beta-oxidase activity.

Catecholamines are degraded in peripheral tissues by catechol-*O*-methyl transferase and monamine oxidase to several metabolites, such as vanillylmandelic acid, metanephrine, and normetanephrine that are excreted in the urine. Measurement of the urinary excretion of these metabolites plus the relatively small amount of free catecholamines excreted in the urine are useful in the diagnosis of certain disorders characterized by overproduction of adrenal medullary hormones. This is best done on urine samples collected over a 24-hour period since catecholamine overproduction often is episodic rather than continuous.

Neoplasms of adrenal medullary secretory cells

Pheochromocytoma and malignant pheochromocytoma

Pheochromocytomas are the most common neoplasms arising in the adrenal medulla of animals. They develop most often in cattle and dogs, and infrequently in other domestic animals. In bulls and humans, pheochromocytomas may develop concurrently with

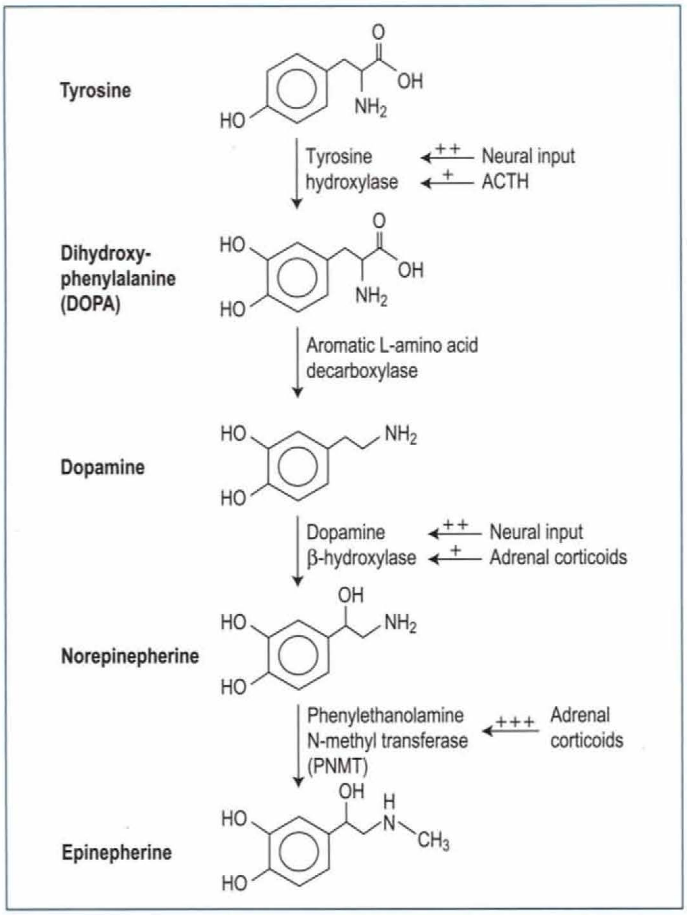

Figure 3.89 Synthesis of norepinephrine and epinephrine in chromaffin cells of the adrenal medulla. Tyrosine hydroxylase is the rate-limiting enzyme. Enzymatic conversion of tyrosine to DOPA and dopamine occurs in the cytoplasm. Synthesis of norepinephrine occurs in the secretory granules, which is the site of dopamine β-hydroxylase. Norepinephrine leaves the secretory granules and is converted to epinephrine in the cytoplasm by phenylethanolamine-N-methyltransferase (PNMT) and then re-enters the secretory granules. (From Rosol TJ, et al. Toxicol Pathol 2001;29:41–48.)

calcitonin-secreting C-cell tumors of the thyroid gland. In some animals, this appears to represent neoplastic transformation of multiple types of endocrine cells of neuroectodermal origin in the same individual. *Malignant pheochromocytoma* often is used to designate medullary tumors that invade through the adrenal capsule and into adjacent structures or that metastasize to distant sites.

Pheochromocytomas are tumors of chromaffin cells and are almost always located in the adrenal gland of animals. They can be either unilateral or bilateral. Although size varies considerably they often are large (10 cm or more in diameter) and incorporate the majority of the affected adrenal gland. A small remnant of the adrenal gland often can be found at one pole (Fig. 3.90A). Smaller tumors are completely surrounded by a thin compressed rim of adrenal cortex. Large pheochromocytomas are multilobular and variegated light brown to yellow-red due to areas of hemorrhage and necrosis. A useful aid in macroscopic diagnosis of pheochromocytoma is the *Henle chromaffin reaction* with either potassium dichromate or iodate. Application of Zenker's solution to the flat-cut surface of a freshly resected tumor results in oxidation of catecholamines, forming a dark-brown pigment within 20 min or less (Fig. 3.90B).

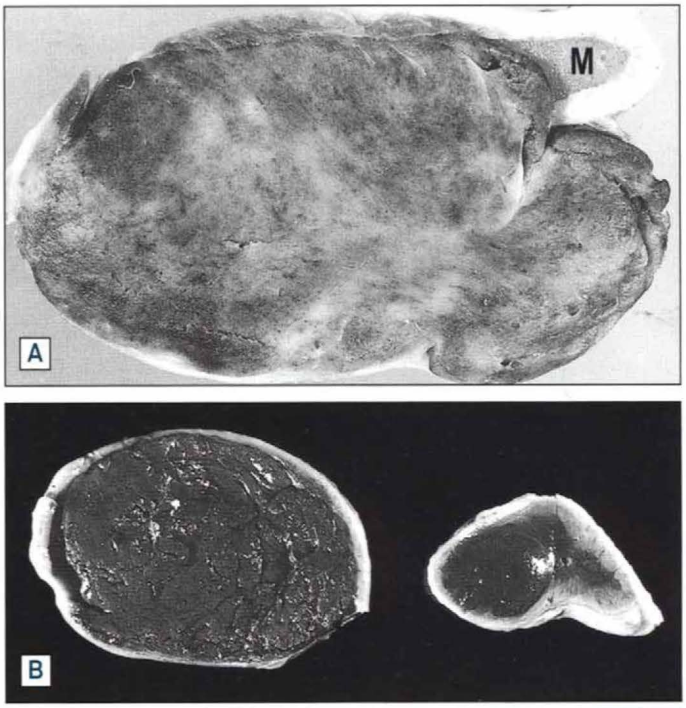

Figure 3.90 A. Pheochromocytoma in a dog with remnant of adrenal medulla (M) at top right. **B.** Chromaffin-positive reaction in bilateral pheochromocytomas, bovine.

Tumor cells in pheochromocytomas vary from small cuboidal or polyhedral cells to large pleomorphic cells with multiple hyperchromatic nuclei. The cytoplasmic area is lightly eosinophilic, finely granular, and plasma membranes often are indistinct because of early onset of autolysis in adrenal medullary tissue. Tumor cells are characteristically subdivided into small lobules by fine connective tissue septa and capillaries (Fig. 3.91A).

Pheochromocytomas are composed of epinephrine-secreting cells, norepinephrine-secreting cells, or both. The principal distinguishing morphologic feature of these two populations of cells is in the fine structure of their secretory granules. Pheochromocytomas from which norepinephrine is the principal catecholamine extracted are composed of cells with secretory granules that have an eccentrically situated electron-dense core surrounded by a wide submembranous space (Fig. 3.91B). When epinephrine is the principal catecholamine the secretion granules in tumor cells have a coarsely granular internal core of lower density and a narrow submembranous space (Fig. 3.91C).

Small pheochromocytomas are well encapsulated and remain confined to the affected adrenal gland. Larger malignant pheochromocytomas may exert pressure on and invade adjacent tissues, particularly the caudal vena cava and aorta. Tumor cells often invade the capsule and penetrate through the wall of the caudal vena cava forming a large thrombus that partially occludes the venous return from the caudal extremities. Metastases occur in ~50% of malignant pheochromocytomas to the liver, regional lymph nodes, spleen, and lungs in dogs. Growth of tumor cells in a subendothelial location along vascular sinusoids and artefactual displacement of clusters of tumor cells into the lumen of thin-walled veins during sectioning and forced through the capsule should not be misinterpreted as evidence of malignancy in adrenal medullary neoplasms (Fig. 3.92).

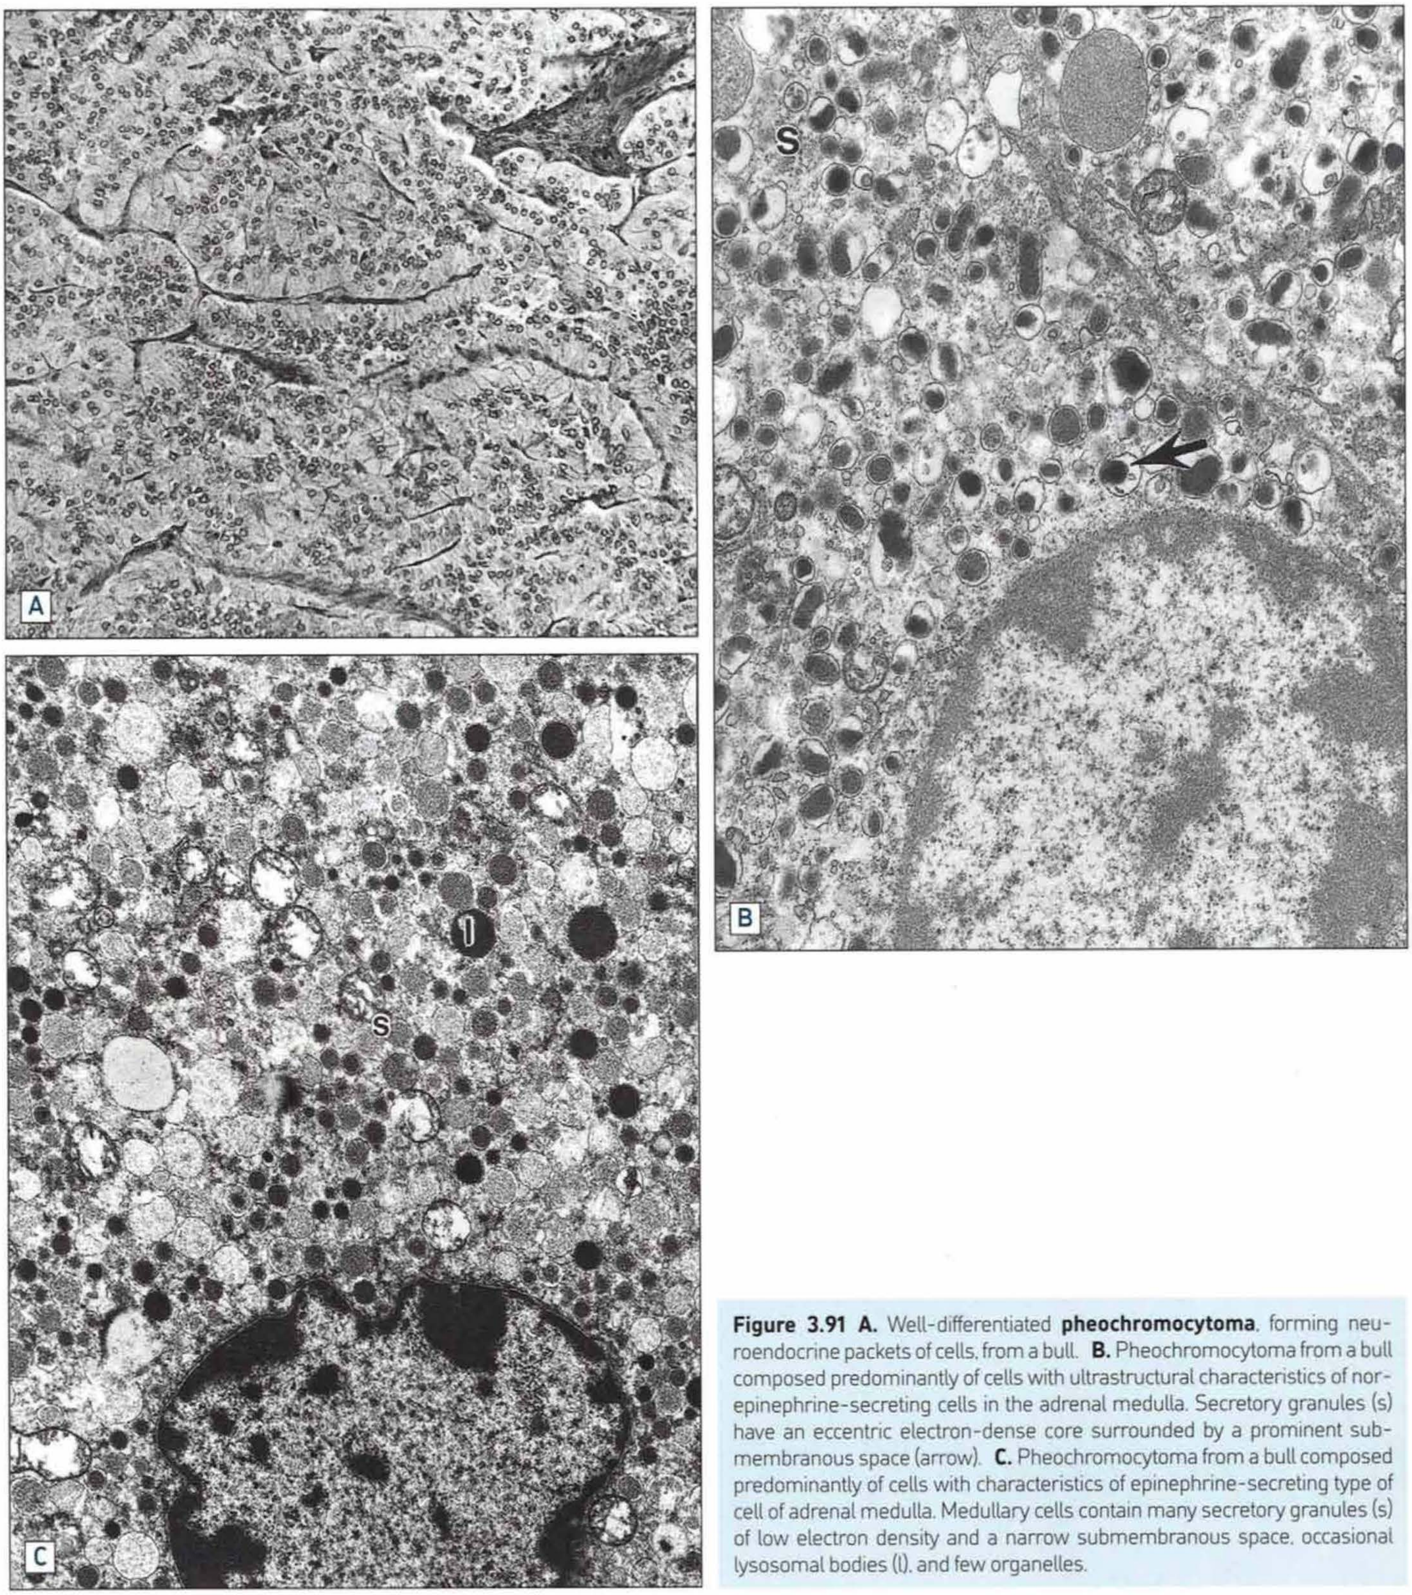

Figure 3.91 A. Well-differentiated **pheochromocytoma**, forming neuroendocrine packets of cells, from a bull. **B.** Pheochromocytoma from a bull composed predominantly of cells with ultrastructural characteristics of norepinephrine-secreting cells in the adrenal medulla. Secretory granules (s) have an eccentric electron-dense core surrounded by a prominent submembranous space (arrow). **C.** Pheochromocytoma from a bull composed predominantly of cells with characteristics of epinephrine-secreting type of cell of adrenal medulla. Medullary cells contain many secretory granules (s) of low electron density and a narrow submembranous space, occasional lysosomal bodies (l), and few organelles.

Functional pheochromocytomas with clinical signs related to catecholamine overproduction occur infrequently in animals. Tachycardia, edema, and cardiac hypertrophy observed in dogs and horses with pheochromocytomas have been attributed to excessive catecholamine secretion. Arteriolar sclerosis and widespread medial hyperplasia of arterioles have been reported in dogs with pheochromocytomas that were associated with clinical signs suggestive of paroxysmal hypertension. The catecholamine content in pheochromocytomas from bulls with concurrent C-cell tumors of the thyroid gland is higher than in the normal bovine adrenal medulla. Urinary excretion of vanillylmandelic acid and free unconjugated catecholamines are elevated in bulls with pheochromocytomas.

Mechanisms of adrenal medullary tumor development

There are *multiple factors* involved in the pathogenesis of pheochromocytomas. This has been most completely studied in laboratory rats. *The factors involved include genetic background, chronic high levels of growth hormone or prolactin associated with pituitary tumors, dietary factors, and stimulation of the autonomic nervous system.* Chronic administration of reserpine to rats results in decreased blood pressure, neural stimulation of the adrenal medulla, and development of hyperplasia and pheochromocytoma. In aged F344 rats, the incidence of pheochromocytoma has been reported to be greater in animals with more severe chronic progressive glomerulopathy. Nutritional factors have an important modulating effect on the spontaneous incidence of adrenal medullary proliferative lesions. Several sugars and sugar alcohols have produced adrenal medullary tumors at high dosages, including xylitol, sorbitol, lacitol, and lactose at concentrations of 10 to 20% in the diet. Although the mechanism involved is not completely understood, a role for calcium has been postulated. High doses of slowly absorbed sugars and starches increase the absorption and urinary excretion of calcium. In addition, vitamin D_3 induces proliferative lesions (hyperplastic nodules and pheochromocytomas) in the rat. Hypercalcemia is known to increase catecholamine synthesis in response to stress, and low-calcium diets will reduce the incidence of adrenal medullary tumors in xylitol-treated rats. Other compounds that might act via altered calcium homeostasis include the retinoids (which can produce hypercalcemia) and conditions such as progressive nephrocalcinosis in aging male rats treated with nonsteroidal anti-inflammatory agents.

Calcium ions as well as cyclic nucleotides and prostaglandins may act as mediators capable of stimulating both hormonal secretion and cellular proliferation. The likelihood of medullary lesions also appears greater in rats with metastatic calcification and nephrocalcinosis. *Vitamin D is the most potent in vivo stimulus yet identified for chromaffin cell proliferation in the adrenal medulla.* Vitamin D_3 (5000; 10 000; or 20 000 IU/kg/day in corn oil) resulted in a 4- to 5-fold increase in bromodeoxyuridine (BrdU) labeling at week 4 that diminished to a 2-fold increase by week 26. An initial preponderance of epinephrine-labeled cells (phenylethanolamine-N-methyl transferase positive (PNMT) cells) subsequently gave way to more norepinephrine-labeled cells. Eighty-nine percent of rats receiving the two highest doses of vitamin D_3 had focal medullary proliferative lesions (BrdU-labeled focal hyperplasias) and pheochromocytomas by week 26 in contrast to absence of medullary lesions in controls. The proliferative lesions usually were multicentric, bilateral, peripheral in location in the medulla, nearly all were PNMT-negative, and appeared to represent morphologic continuum rather than separate entities. Earlier studies had demonstrated that the vitamin D_3-induced increase in chromaffin cell proliferation was observed as early as 1 week but had declined by 4 weeks. These findings support the hypothesis that altered calcium homeostasis is indirectly involved in the pathogenesis of pheochromocytomas in rodents, most likely via effects on increasing chromaffin cell proliferation. Vitamin D_3, lactose, and xylitol all failed to stimulate directly the proliferation of chromaffin cells in vitro.

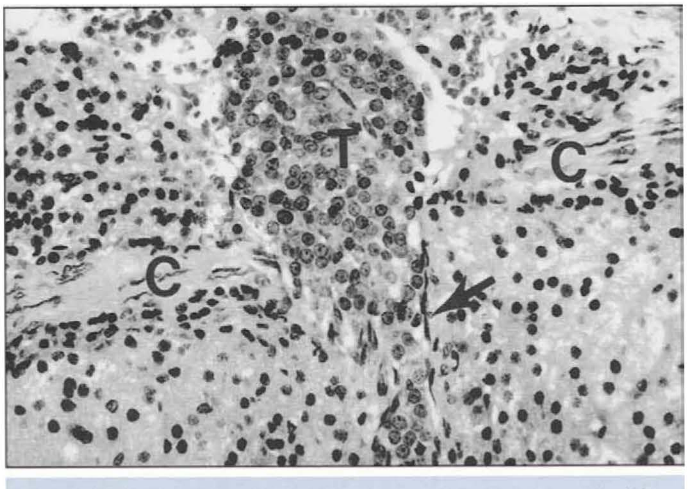

Figure 3.92 Pheochromocytoma from a rat. Tumor cell thrombus (T) in endothelial cell-lined adrenal vein passing through adrenal capsule C. The thrombus likely was artefactually forced through the capsule (arrow) during sectioning of the enlarged adrenal gland.

Adrenal medullary hyperplasia

Diffuse or nodular adrenal medullary hyperplasia appears to precede the development of pheochromocytoma in bulls, humans with C-cell tumors of the thyroid gland, and laboratory rats. Diffuse proliferation of chromaffin cells is non-encapsulated but compresses the surrounding adrenal cortex (Fig. 3.93). The hyperplastic cells are columnar to cuboidal and have a lightly basophilic cytoplasm. Bulls with prominent diffuse medullary hyperplasia often have a few small foci of intense nodular (focal) proliferation of medullary cells. Medullary hyperplasia is detected by increased total adrenal weight, a decrease in corticomedullary ratio due to an increase in the size and number of medullary cells, and the presence of frequent mitotic figures in the adrenal medulla.

Neoplasms of cells of the sympathetic nervous system in adrenal medulla

Neuroblastoma

Neuroblastomas arise from primitive neuroectodermal cells, often in younger animals, and form a large intraabdominal mass. They are differentiated from pheochromocytomas by being composed of small tumor cells with hyperchromatic nuclei and scant amounts of cytoplasm that often resemble lymphocytes and tend to form pseudorosettes (Fig. 3.94). Neurofibrils or unmyelinated nerve fibers can be demonstrated in neuroblastomas.

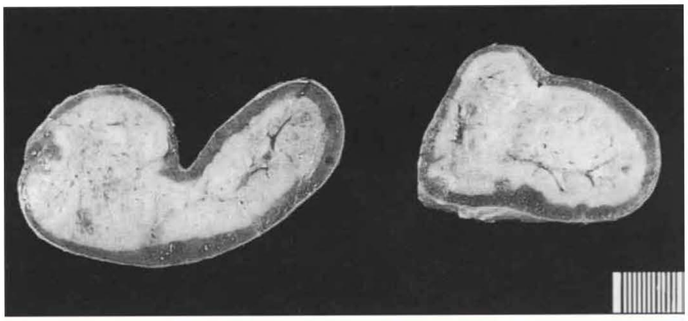

Figure 3.93 Bilateral diffuse hyperplasia of adrenal medulla from a bull. Scale in mm. (From Yarrington JT, Capen CC. Vet Pathol 1981;18:316–325.)

Ganglioneuroma

Ganglioneuromas are benign tumors in the medulla composed of multipolar ganglion cells and neurofibrils with a prominent fibrous connective tissue stroma (Fig. 3.95A–C). They usually are well-differentiated small tumors that in cattle often contain melanin pigment. The surrounding adrenal cortex is compressed to various degrees depending upon the size of the tumors. Neoplastic cells in medullary tumors occasionally may differentiate in two directions resulting in adjacent pheochromocytomas and ganglioneuromas in the same adrenal gland.

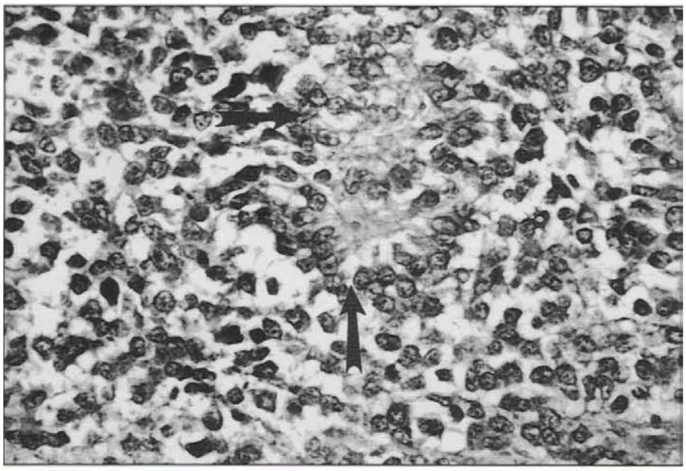

Figure 3.94 Neuroblastoma in a canine adrenal gland, with pseudorosette formation (arrow). The tumor cells have small hyperchromatic nuclei and poorly defined cytoplasm. (From Capen CC. In: Tumors of Domestic Animals, 4th ed., 2002.)

Metastatic tumors of the adrenal medulla

Secondary foci of neoplastic growth in the adrenal glands are common in cases of disseminated neoplasia and originate primarily as tumor cell emboli. The metastases usually are bilateral and the medulla is an early site of tumor growth due to the low-pressure venous blood supply. Direct invasion of the adrenal glands may occur from primary or secondary tumors of contiguous structures; however, direct invasion is uncommon due to the adrenal capsule.

Involvement of the adrenal glands by lymphosarcoma and mammary carcinoma may be extensive, and both adrenals are likely to be affected. Tumor emboli lodge in sinusoids of the adrenal medulla and may grow to an extent that they compress the surrounding adrenal cortex.

CHEMORECEPTOR ORGANS

Development, structure, and function

The chemoreceptor organs (*nonchromaffin extra-adrenal paraganglia*) are sensitive to changes in the blood carbon dioxide content, pH, and oxygen tension, thereby aiding in the regulation of respiration and circulation. **Carotid and aortic bodies** can initiate an increase in the depth, minute volume, and rate of respiration by way of parasympathetic nerves and result in an increased heart rate and elevated arterial blood pressure by way of the sympathetic nervous system. *They are composed normally of parenchymal (chemoreceptor, glomus) cells and stellate (sustentacular) cells.* Nerve endings with synaptic vesicles as well as nerve fibers are seen in close association with the chemoreceptor cells.

Chemoreceptor tissue is present at several *sites* in the body including the carotid body, aortic bodies, nodose ganglion of the vagus nerve, ciliary ganglion in the orbit, pancreas, bodies on the internal jugular vein below the middle ear, and glomus jugulare along the recurrent branch of the glossopharyngeal nerve. Aortic bodies of dogs normally consist of clusters of cells embedded in adventitia at multiple sites including the innominate artery immediately below the origin of the right subclavian artery, on the cranial surface of the aortic arch, beneath the arch between the aorta and pulmonary artery, between the ascending aorta and pulmonary artery near the left coronary artery, and scattered in the wall of the pulmonary artery. Although chemoreceptor tissue appears to be widely distributed in the body, *tumors develop principally in the aortic and carotid bodies of animals.*

Aortic body adenoma and carcinoma

Aortic body neoplasms are encountered more frequently than neoplasms of the carotid body in animals, but the reverse is true for humans. These tumors develop primarily in dogs, and infrequently in cats and cattle. Brachycephalic breeds of dogs such as the Boxer and Boston Terrier are highly predisposed to develop tumors of the aortic and carotid bodies.

Aortic body tumors appear most frequently either as single masses or as multiple nodules within the pericardial sac near the base of the heart (Fig. 3.96). They vary considerably in size (0.5–12.5 cm) with carcinomas, in general, being larger than adenomas. Solitary small **aortic body adenomas** either are attached to the adventitia of the

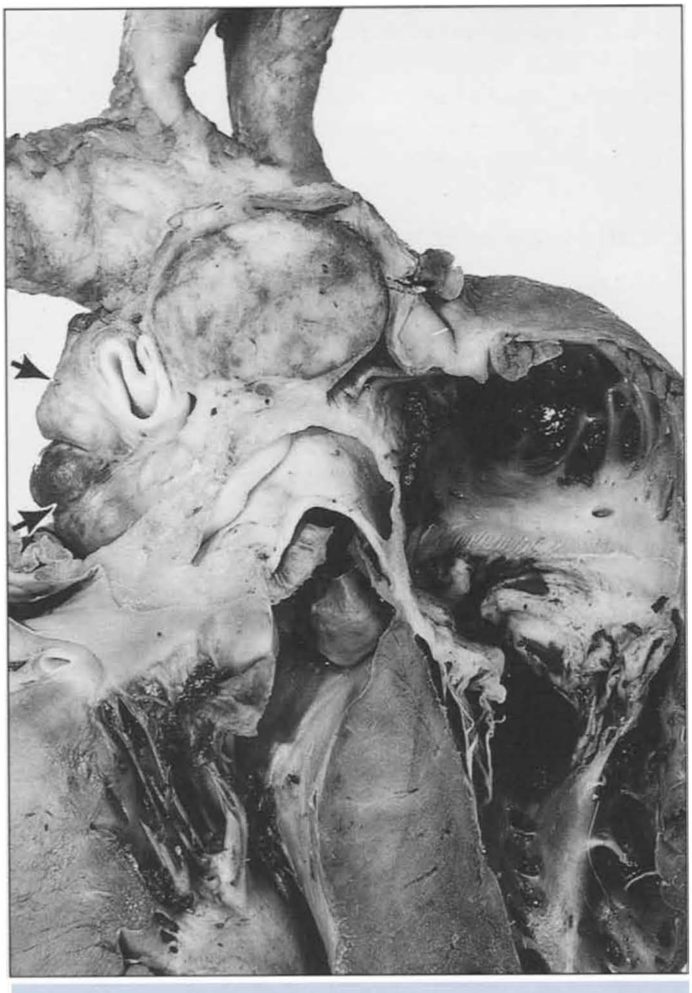

Figure 3.96 Aortic body tumors (arrows) at base of heart of a dog.

pulmonary artery and ascending aorta or are embedded in the adipose connective tissue between these major vascular trunks. They have a smooth external surface and on cross-section are white, mottled with red-to-brown areas. Larger adenomas may indent the atria or displace the trachea, are multilobular, and partially surround the major arterial trunks at the base of the heart. Although the vessels may be completely surrounded by neoplastic tissue, there usually is little evidence of vascular constriction.

Aortic body carcinomas occur less frequently in dogs than adenomas. Carcinomas may infiltrate the wall of the pulmonary artery to form papillary projections into the lumen or invade through the wall into the lumen of the atria. Although tumor cells often invade blood vessels, metastases to the lung and liver occur infrequently.

Aortic body tumors in animals tend to be more benign than tumors of the carotid body. They grow slowly by expansion and exert pressure on the vena cava and atria. Aortic body carcinomas may invade locally into the atria, pericardium, and adjacent large thin-walled vessels. When they metastasize, secondary foci of growth are found most frequently in the lung and liver.

Tumors of the aortic bodies in animals are not functional (i.e., they do not secrete excess hormone into the circulation), but may result in a variety of functional disturbances as *space-occupying lesions*. These include manifestations of cardiac decompensation due to pressure on the atria, vena cava or both associated with larger aortic body adenomas and carcinomas. There may be dyspnea, coughing, vomiting, cyanosis, hydrothorax, hydropericardium, ascites, edema of the subcutaneous tissue (involving head, neck, and forelimbs), and passive congestion of the liver. The accumulation of serous, often blood-tinged, fluid in the pericardial sac results from the invasion of tumor cells into lymphatics at the base of the heart or the compression of small pericardial veins.

Carotid body adenoma and carcinoma

Carotid body neoplasms arise near the bifurcation of the common carotid artery in the cranial cervical area. They usually appear as a unilateral slow-growing mass and only rarely develop on both sides in the same animal.

Carotid body adenomas are well encapsulated, have a smooth external surface, and vary from 1 to 4 cm in diameter. The bifurcation of the carotid artery is incorporated in the mass, and tumor cells adhere firmly to the tunica adventitia. A branch of the glossopharyngeal nerve may be traced into the capsule of the tumor by careful dissection. Adenomas are firm, white with scattered areas of hemorrhage, and extremely vascular. Complete surgical excision or biopsy often is difficult due to the high degree of vascularity and intimate relationship with major arterial trunks in the neck.

Carotid body carcinomas are larger (up to 12 cm in diameter) and more coarsely multinodular than adenomas. Although malignant carotid body tumors appear to be encapsulated, tumor cells invade the capsule and penetrate into the walls of adjacent vessels and lymphatics. The external jugular vein and several cranial nerves (in addition to the carotid bifurcation) may be incorporated by the neoplasm. Larger tumors can result in extensive dorsolateral deviation of the trachea. Metastases of carotid body tumors occur in about one third of cases, and have been found in the lung, bronchial and mediastinal lymph nodes, liver, pancreas, and kidney. *Multicentric neoplastic transformation of chemoreceptor tissue occurs frequently in brachycephalic breeds of dogs.* About two thirds of the reported cases of carotid body tumors also had aortic body tumors.

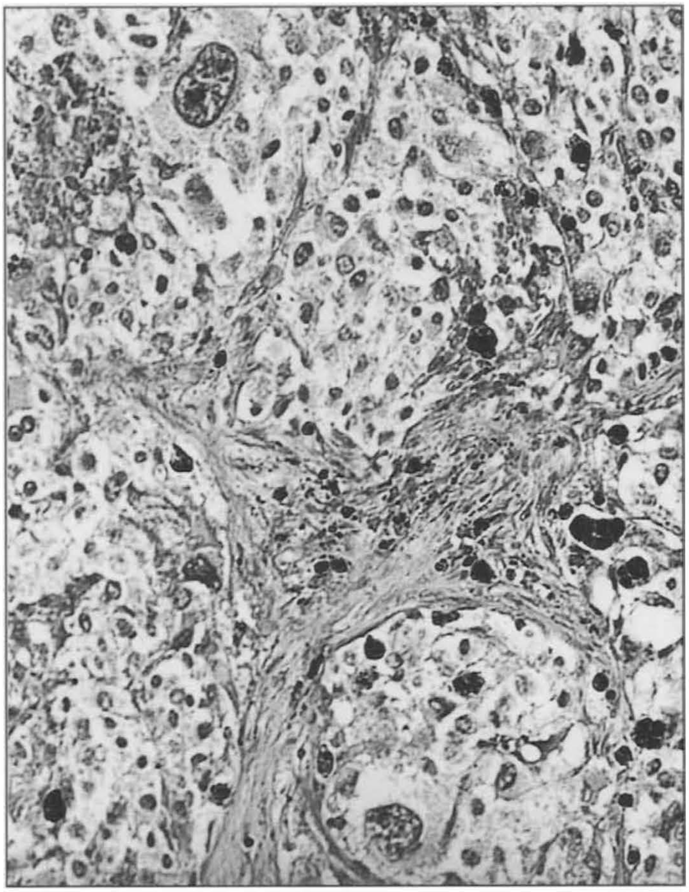

Figure 3.97 Cellular pleomorphism in a **carotid body tumor** from a dog.

The histologic characteristics of chemoreceptor tumors ("chemodectomas") are essentially similar whether they are derived from the carotid or aortic body. The neoplastic chemoreceptor cells are subdivided into lobules by prominent branching trabeculae of connective tissue that originate from the fibrous capsule (Fig. 3.97). They are further subdivided into small compartments by fine septa that contain collagen and reticulin fibers plus small capillaries. Tumor cells are commonly aligned along and around small capillaries.

The tumor cells of chemodectomas are discrete, cuboidal to polyhedral, and closely packed together. The cytoplasm is lightly eosinophilic, finely granular, and often vacuolated. Cells comprising chemodectomas rapidly undergo autolysis. Cell boundaries become indistinct and the cytoplasm appears clear if the postmortem interval is prolonged. *Chromaffin granules cannot be demonstrated in the cytoplasm of cells comprising chemodectomas*, in contrast to pheochromocytomas of the adrenal medulla.

Cells of aortic and carotid body tumors in the dog resemble those in normal chemoreceptor tissue, but lack the normal relationship to sustentacular, neural, and vascular elements. The large polyhedral chemoreceptor or parenchymal cells are arranged in small clusters. The cytoplasmic density of the neoplastic cell varies from light to dark depending on the development of secretory organelles and numbers of storage granules. Small spherical mitochondria, parallel arrays of rough endoplasmic reticulum, and Golgi apparatuses with prosecretory granules are scattered in the cytoplasm.

Variable numbers of small, electron-dense, membrane-limited secretory granules are present in the tumor cells and are important in establishing the diagnosis of an aortic or carotid body tumor. The electron density of secretory granules in chemoreceptor cells varies considerably with the fixative used, but the granules are well preserved with glutaraldehyde. In general, secretory granules are more numerous in cells of adenomas than in those of carcinomas of the aortic and carotid bodies. Stellate cells often extend long cytoplasmic processes around and between the tumor cells in carotid body adenomas from dogs. These processes appear to terminate near perivascular spaces. Similar sustentacular cells have been described in the carotid body of normal animals and are considered to have a supportive rather than a secretory function. *Ultrastructural studies are helpful in differentiating between heart-base tumors derived from chemoreceptor cells of the aortic body and ectopic thyroid follicular cells in the dog.* The neoplastic follicular cells are arranged predominantly in a compact cellular (solid) pattern with only an occasional colloid-containing follicle, and they may closely resemble an aortic body tumor. Although thyroid follicular cells contain large lysosomal (dense) bodies, they lack the small membrane-limited secretory granules characteristic of chemoreceptor cells in the aortic and carotid bodies.

Carotid body tumors are very vascular and have numerous muscular arterioles, large thin-walled veins, and an abundant network of capillaries in the connective tissue septa. There are focal areas of hemorrhage from disruption of thin-walled vessels and areas of coagulation necrosis. Several layers of tumor cells may radiate along fine connective tissue septa from the thin-walled vessels. Tumor cells frequently invade blood vessels and lymphatics with the formation of emboli. Carcinomas have evidence of tumor cell invasion through the capsule and into the walls of large muscular arteries and adjacent structures.

Dogs with carotid body tumors usually are presented with a palpable, slowly enlarging mass in the craniolateral cervical region near the angle of the mandible. Larger neoplasms interfere with swallowing due to pressure on the esophagus and result in circulatory disturbances from compression of the larger veins in the neck. Other functional disturbances may be related to the presence of an aortic body tumor in the same animal.

Carotid body tumors tend to be more malignant than aortic body tumors, and metastases are present in about one third of reported cases. The presence of tumor cell emboli in vascular or lymphatic spaces in a biopsy of a primary chemodectoma does not necessarily indicate that metastases are present in distant organs.

The etiology of carotid and aortic body tumors is unknown, but it has been suggested that a *genetic predisposition aggravated by chronic hypoxia* may account for the higher risk of certain brachycephalic breeds such as the Boxer and Boston Terrier. Carotid bodies of several mammalian species, including dogs, undergo hyperplasia when subjected to chronic hypoxia by living in a high-altitude environment. People living at high altitudes have 10 times the frequency of chemodectomas of those living at sea level.

Heart-base tumors derived from ectopic thyroid

Adenomas and carcinomas derived from ectopic thyroid tissue account for ~5–10% of "heart-base" tumors in dogs. They often compress or invade structures in the cranial mediastinum near the base of the heart. Areas of ectopic thyroid tumors with a compact cellular (solid) pattern of arrangement are difficult to distinguish histologically from aortic body tumors. *Cells comprising ectopic thyroid tumors generally are smaller than in aortic body tumors, with more hyperchromatic nuclei and eosinophilic cytoplasm.*

Neoplastic thyroid follicular cells are not consistently subdivided into small packets by fine strands of connective tissue. Tumor giant cells are infrequent in ectopic thyroid tumors and the stroma is less prominent. Multiple sections usually reveal the formation of *primitive follicular structures or colloid-containing follicles* by neoplastic follicular cells in ectopic thyroid tumors but not in aortic body tumors. Ectopic thyroid carcinomas arising at the base of the heart in dogs either remain localized and enlarge in the cranial mediastinum or occasionally metastasize to extrathoracic sites.

Orbital (extra-adrenal) paragangliomas (neuroendocrine tumors)

A unique extra-adrenal paraganglioma occurs in *horses*, resulting primarily in clinical signs related to *exophthalmos*. The lesion appears to be derived from cells of neural crest origin, most likely nonchromaffin paraganglia near the ciliary ganglion. The neoplastic cells usually invade locally in the retrobulbar space but may infiltrate more aggressively through the optic canal into the cranial vault resulting in lysis of bone and extension into the nasal cavity.

The tumors are densely cellular with nests or packets of neoplastic cells subdivided by a fine fibrovascular (reticulin-positive) stroma characteristic of neuroectodermal-derived tumors. The cytoplasmic area is abundant, lightly eosinophilic, and finely granular, often with indistinct individual cell boundaries. The neoplastic cells have a positive argyrophilic reaction (either by Pascual's silver inpregnation method or the Grimelius technique), stain positive by immunohistochemical methods for chromogranin A and neuron-specific enolase, but are negative for S-100 protein and glial fibrillary acidic protein. Ultrastructurally, neoplastic cells of orbital paragangliomas in horses are similar to those in canine aortic and carotid body tumors, with typical membrane-bound secretory granules and prominent arrays of rough endoplasmic reticulum.

Surgical removal of the tumors by transpalpebral orbital exenteration has been performed with variable success depending upon the degree of local tissue invasion of the tumor beyond the orbit. Manipulation of the tumors during surgery may result in hypotension.

Pathology of the genital system of the nongravid female

GENERAL INTRODUCTION

Unique challenges associated with pathology of the female reproductive system

In no other system does one commonly encounter so great a variety of gross and microscopic changes in "normal" tissues as those that are routinely encountered in reproductive organs in the normal cycling and gravid female. The complex physiologic events that are associated within the estrus cycle, in pregnancy, or during the postpartum periods are accompanied by dramatic tissue changes in the gonads, tubular, and external genitalia, such as marked hyperplasia, atrophy, necrosis, hemorrhage, and tissue invasion. These are changes that pathologists usually associate with pathological processes. Consequently, when presented with reproductive tissues, an examining pathologist must start with a firm understanding of the normal embryology, anatomy, and reproductive physiology associated with the species under study.

Remarkable species variations exist, which limits the usefulness of broad generalizations and makes casual extrapolations fraught with error. A good clinical history that includes stage of cycle, prior reproductive status, and supporting endocrinology is especially important; if not provided, it should be aggressively sought!

It must also be appreciated that, to a significant extent, the commercial value of individual animals can depend on the pathologist's report (for example, endometrial biopsy from a broodmare). Not only do the descriptive and diagnostic sections of the report have to be accurate and precise, clinicians and owners will likely place great weight on the pathologist's interpretation and assessment of clinical significance. This part of the report must be carefully formulated.

Pathology of the reproductive system is unquestionably both fascinating and challenging.

SEXUAL DEVELOPMENT AND ANOMALIES ASSOCIATED WITH SEXUAL DIFFERENTIATION

Abnormalities of sexual development are relatively common and affect all domestic animal species. Although the majority of these do not affect reproductive performance and are considered incidental findings, their presence can add confusion when confronted during clinical examinations (for example, detection of cysts in or near the ovary during ultrasound examination), and during routine surgery or postmortem examinations. Basic knowledge of the normal process of sexual differentiation, including a full appreciation of the anatomical changes that occur, is essential for the pathologist doing routine diagnostic pathology. The first section of this chapter provides a brief overview of normal sexual development. This is followed by a discussion of frequently encountered lesions associated with anomalous development of reproductive organs.

Normal sexual differentiation

Knowledge of the essential elements of the developmental anatomy of the reproductive organs is important for appreciation of the anatomy and histology of the gonads, tubular and external genitalia of the female, and is essential for comprehension and interpretation of congenital anomalies, the histogenesis of various neoplasms, or the pathogenesis of many other ovarian lesions (e.g., cysts, abnormalities of placentation).

Stage of sexual development

There are **three essential sequential series of events** that occur during **normal sexual development**:

1. The initial **establishment of genetic sex** (at fertilization).
2. The subsequent modeling of embryonic gonadal tissue as ovarian tissue, thereby **establishing gonadal sex**.
3. Controlled, programmed regression and growth of different parts of the indifferent tubular and external genital tissues of the early embryo to form those definitive structures that constitute the normal female reproductive pattern (the female phenotype). This is referred to as the **establishment of phenotypic sex**.

Establishment of genetic sex

The determination of genetic sex is fixed at the time of fertilization when egg and sperm unite. The genetic sex, or chromosomal sex, as it is sometime referred to, is then imposed on the undifferentiated indifferent gonad and thus the sequence of stages in sexual development progresses.

Each embryo will have either XX (in females) or XY (in males) sex chromosomes. These chromosomes carry many different genes required for sexual development, and recent research has shown that these genes interact as cascades, with certain genes acting as controlling, or master genes. Aberrations in genes associated with sexual differentiation, therefore, can lead to a broad variety of developmental anomalies. Knowledge gained through study of spontaneous cases of abnormal sexual differentiation in animals and humans has been greatly expanded through work using engineered mutations in mice. However, the precise mechanisms through which genes control each aspect of sexual differentiation are complex and only superficially understood.

It has been known for some time that the Y chromosome contains the genes that regulate differentiation leading to the male phenotype. Those genes responsible were postulated to be the **testis-determining factor(s)** of the Y chromosome, with the inference that it would be shown to be a single gene. This gene has been called the *SRY* gene (sex-determining region of the Y chromosome). The list of genes that when mutated involve anomalies in sex differentiation is continuously expanding. These include *WT1, Sf-1, SOX9, DAX1, SRY, MIS,* and *AR*. The genetics of gonadal development is complex and beyond the scope of this chapter (see MacLaughlin and Donahoe, in the Bibliography below).

Development of gonadal sex

Growth and development of the gonads require a complex series of steps that are only slowly becoming evident. The ovary arises from paired gonadal primordia called the *genital ridges* located between the mesonephros and attachment of the mesentery. Primordial germ cells migrate to the developing indifferent gonad through the wall of the yolk sac and the wall of the hindgut to become associated with primitive sex cords. *The sex cords go on later to organize as follicles containing the germ cells.*

In a normal XX female embryo, the outer cortical layer of the indifferent gonad becomes the ovary, while the medullary region of the indifferent gonad develops as the testis in normal male (XY) embryos. It is necessary to appreciate this to understand the range of abnormalities in gonadal developments in intersex animals. *Gonadal hormones (limited to products from testicular tissue) control subsequent differentiation of the rest of the reproductive organs.* Only hormones produced by testicular tissue act to control further modeling of the tubular and external genitalia. Female sexual differentiation does not require products from the fetal ovary. A male fetus castrated in utero early in development, although a genetic male, will develop female internal and external organs and appear as a phenotypic female.

The two critical products originating from the fetal testis are both hormones: **Müllerian inhibitory substance (MIS)** and **testosterone**.

Phenotypic sexual development

Female tubular and external genital development progresses in genetic female embryos only in the absence of hormones, whereas in the male, *MIS and testosterone function to force tissues of the indifferent, early embryo towards differentiation into male structures.* These hormones influence the regression of female embryonic tubular structures and support the formation of male tubular organs (epididymis, vas, accessory sex glands) and stimulate the progressive development of the genital tubercle to become the penis, the genital folds to close as the prepuce, and the genital sinus to differentiate into the pelvic structures.

Modeling of the tubular genitalia involves growth, fusion, and extension of the embryonic paramesonephric ductal system to form the internal female nongonadal organs (uterus, cervix, and cranial vagina); and changes in the urogenital recess, genital tubercle, and genital folds to form the vulva, clitoris, vestibule, and caudal vagina. The presence of androgens, either endogenous (from testicular tissue, for example in intersex individuals with ovotestes) or from exogenous sources (androgens administered during pregnancy) can influence this development, leading to partially masculinized females (*ambiguous genitalia*).

Development of the tubular genitalia

Even as the indifferent gonads are developing from the genital ridge, in embryos destined to become females, cylindrical (ductal and tubular) elements are forming in the abdomen that will further differentiate into the tubular genitalia.

During the early stages, male embryos and female embryos contain the same tissues and cannot be differentiated based on morphology. Paired **mesonephric (Wolffian) ducts** arise from primitive renal tissues and paired **paramesonephric (Müllerian) ducts** form de novo from longitudinal folds along the lateral inner abdominal wall (Fig. 4.1). Tubules branching from the cranial segment of the mesonephric ducts contribute to development of the rete and sex cords.

The mesonephric and paramesonephric ducts run parallel to one another. Both ductal systems are symmetrically paired and extend caudally toward the urogenital sinus. The cranial ends of the developing paramesonephric ducts do not close and open directly into the peritoneal cavity, corresponding to the tissue that will become

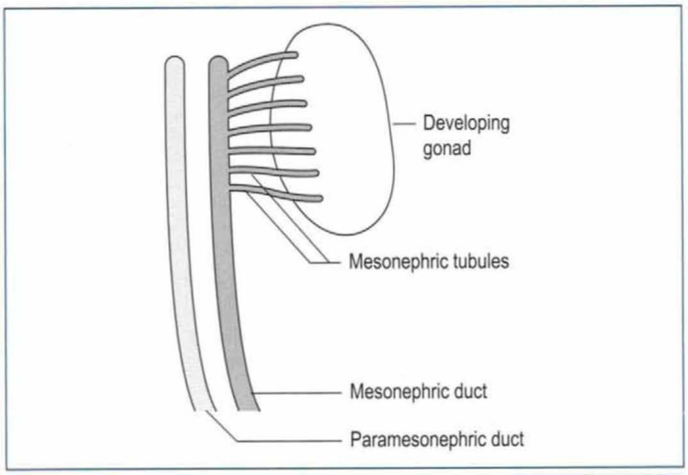

Figure 4.1 Embryonic development of the female genital system. Initial development of the indifferent ducts, tubules, and external genitalia is the same in male and female embryos. Anatomically, the internal organs in the indifferent stage consist of two bilaterally symmetrical ductal systems, the mesonephric (Wolffian; male) and paramesonephric (Müllerian; female) ducts, and the developing, but uncommitted, gonad. Additionally, the mesonephric duct develops tubular extensions at its cranial end that extend into the hilar area of the gonad. In the male, these will become the rete and the efferent tubules of the epididymis. Although the uterine tubes, uterine horns, body, cervix, and cranial vagina develop from the paramesonephric duct, the mesonephric tubes become the rete and contribute to the sex cords of the ovary. Normally, the ducts of the opposite sex regress; however, their embryonic remnants are frequently encountered in otherwise normal adult animals, and are also present as cystic structures in or near the ovary, uterus, cervix, or vagina. (Illustration prepared by Mr. Michael Simmon.)

the fimbrial part of the uterine tube. In domestic animals, the paramesonephric ducts fuse at their caudal ends to form the body of the uterus, the cervix, and the cranial vagina, each with a single lumen.

Female differentiation occurs in the absence of a functional male gonad. Sexual development in all individuals would be feminine if not prevented by the influence of two hormones produced by the embryonic testis. An important feature of gonadal differentiation is the chronological differences that exist between the sexes. In all mammalian species studied, *males differentiate earlier than females.*

Masculine differentiation is imposed on the system at an early stage by testosterone produced by the Leydig cells of the developing testis. The second hormone critical for normal male differentiation, MIS, is produced by sustentacular (Sertoli) cells of the developing testis. MIS causes the paramesonephric (Müllerian) ducts to regress, leaving only the mesonephric ducts and tubules to grow and differentiate. The presence of an embryonic testis producing testosterone supports further differentiation of mesonephric duct growth to become the vasa deferentia, seminal vesicles, and the epididymides. Testosterone also plays a central role in the development of the external genitalia. Testosterone is converted to dihydrotestosterone by 5α-reductase, and this hormone induces development of the penis and scrotum from the bipotential external genital primordia. In a female, in the absence of testosterone or MIS, the mesonephric ducts atrophy, the paramesonephric ducts become the uterine tubes, horns and body, cervix, and cranial vagina, and the indifferent external genitalia become the vulva, clitoris, vestibule, and caudal vagina.

Abnormalities of sexual development

Disorders of genital development occur in all domestic species, but are common in none. They are caused by abnormalities of genetic or chromosomal origin or inappropriate hormone exposure. The mechanisms involved in the production of many abnormalities are not known and a condition cannot often be classified precisely. *Hermaphroditism is a broad grouping.* **Hermaphrodites** have ambiguous genitalia, with part or all of the genital organs of both sexes present. The intersex is subclassified into true and pseudo, the distinction being based on the *presence of both types of gonadal tissue in the true hermaphrodite.* The **pseudohermaphrodite** has only a single type of gonadal tissue and the individual is classified as either a male or female pseudohermaphrodite on the basis of the gonadal tissue present. These terms serve only limited goals of description. The application of sophisticated techniques to the study of abnormal sexual development has elucidated, in some cases, the mechanism by which the anomalies developed, and as well has clarified some of the intricate hormonal and genetic mechanisms by which normal sexual development occurs.

Intersex conditions

Abnormal sexual differentiation commonly results in abnormal-appearing external genitalia. Some of the more dramatic examples of this occur in intersex animals that commonly have ambiguous external genitalia. As demonstrated in Figure 4.2, a photo of an intersex mare with bilateral ovotestes, the external genitalia have features that are partially female and partially male. Testosterone produced by testicular tissues (interstitial cells) of her ovotestes masculinized her external genitalia. The vulva is located more ventrally than in a normal female, the vulvar lips are variably fused, and there is clitoromegaly. In true hermaphrodite bitches, owners frequently observe an abnormally enlarged clitoris that may protrude from the vulva. Less subtle cases may be presented in fertility work-ups. The spectrum of changes ranges from nearly normal-appearing females, with grossly normal ovaries and uteri, to males with small genitalia, perhaps hypospadias, and gonads contained in scrotal sacs that look like testes with epididymides, but histologically containing ovarian tissue.

It is not uncommon to find normal-appearing testes attached to complete and well-formed uterine horns in intersex bitches (Fig. 4.3).

Ovotestes will contain both ovarian and testicular tissues (Fig. 4.4). It is not uncommon to find secondary or antral follicles, and occasionally follicles can ovulate, and there may be corpora lutea in gonads that also contain male (seminiferous and interstitial) tissue.

Ovotestes will vary greatly in both their gross and microscopic appearance, depending on the relative amounts of ovarian and testicular tissue present (Fig. 4.5). Ovotestes composed predominantly of ovarian tissues are usually contained in a bursa. There may be identifiable epididymal tissues at the caudal pole, near the attachment of the proper ligament of the ovary. Ovotestes composed of mostly testicular tissue will look like hypoplastic testes, have large epididymides, and may be near or in the inguinal canal or scrotal sac. They will, however, be attached to uterine horns.

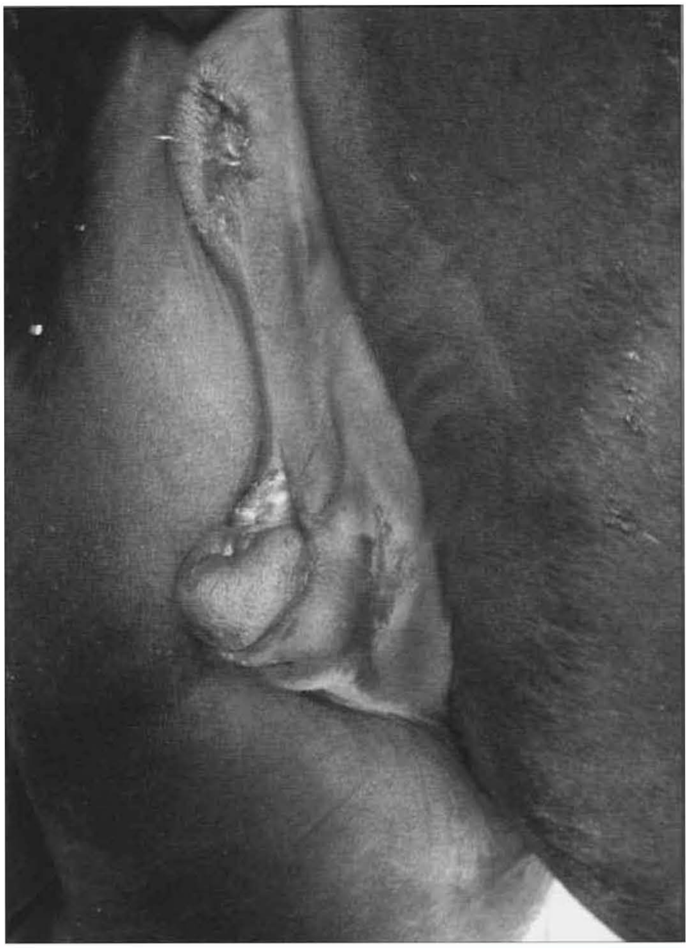

Figure 4.2 The **external genitalia of an intersex horse** with clitoromegaly and partial fusion of the vulvar lips. The external female genitalia were partially masculinized from exposure to testosterone released from testicular tissue (interstitial cells) from her ovotestes during embryonic development.

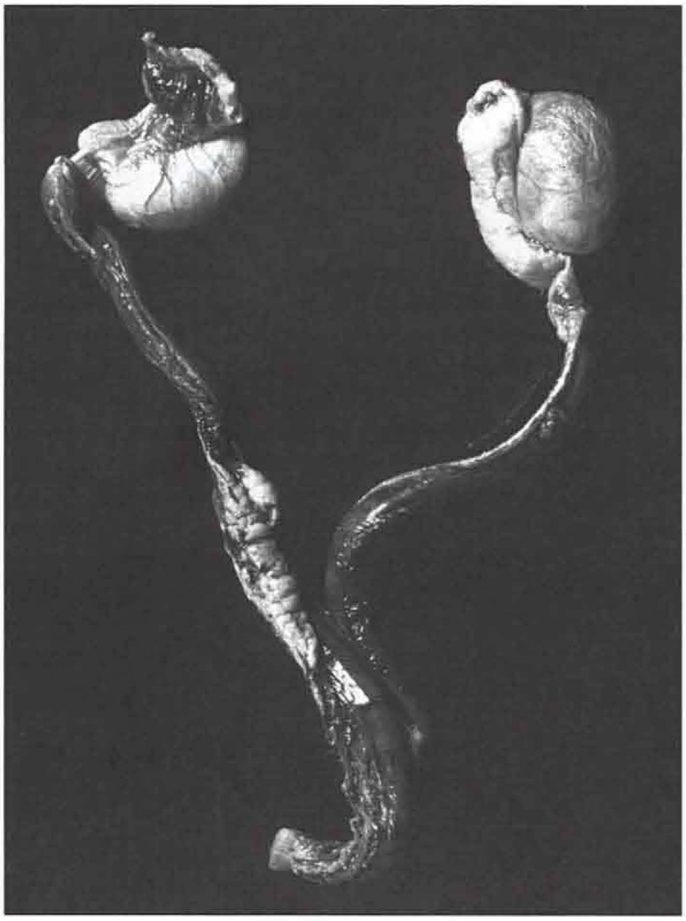

Figure 4.3 Internal reproductive organs from an **intersex bitch** revealing a near normally formed, but hypoplastic, uterus (paramesonephric duct derived) with bilateral ovotestes that are predominantly testicular with attached epididymis (derived from mesonephric tubules).

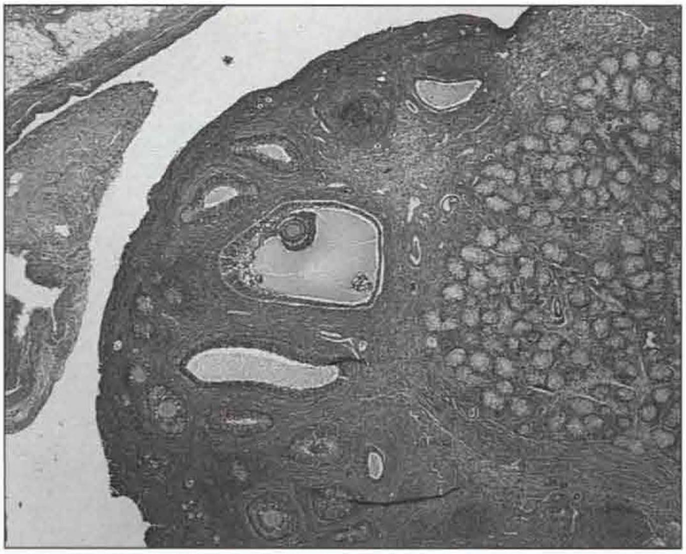

Figure 4.4 Section of **ovotestis from an intersex bitch**. The gonad is contained within a bursa (visible on the left) and has both ovarian tissue (with primary and antral follicles on the left) and lobules of hypoplastic testicular tissue in the medullary area (on the right). Even relatively small areas of testicular tissue in ovotestes produce sufficient amounts of two hormones, testosterone from the interstitial cells and Müllerian inhibitory substance from Sertoli cells, that act during early gestation to masculinize the developing mesonephric and paramesonephric ducts and tubules and the external genitalia.

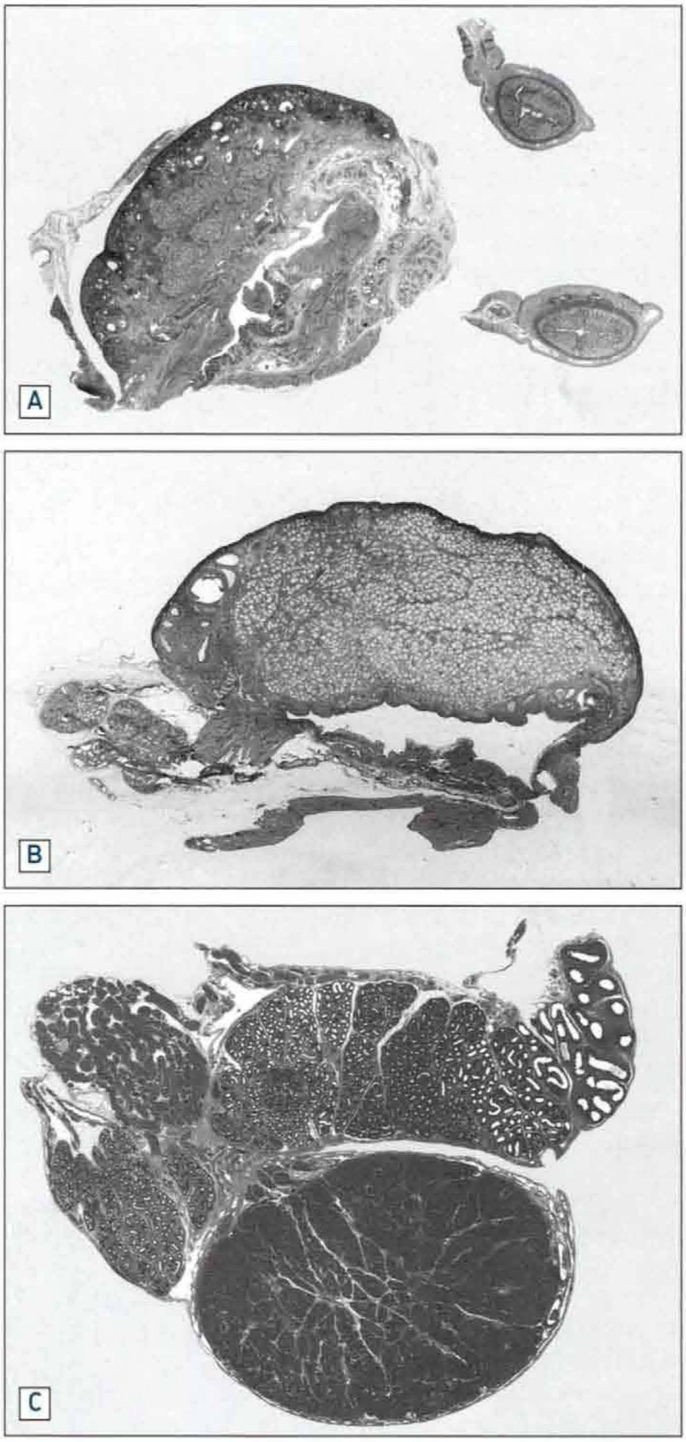

Figure 4.5 Ovotestes from intersex bitches. These three subgross photographs of gonadal sections demonstrate the variability in amounts of ovarian and testicular tissue found in ovotestes. An important pattern to recognize is that ovarian tissues will be found in the cortex and testicular tissues in the medulla. **A.** The ovotestis is mostly ovarian with only a few lobules of hypoplastic seminiferous tubules in the medulla. **B.** The ovotestis is mostly testicular tissue (seminiferous tubules forming a lobular pattern), but also note the presence of antral follicles in the ovarian tissue at the left pole. **C.** The ovotestis is nearly entirely testicular and has a large epididymis attached.

In the canine species, ovotestes are commonly contained within a bursa, and careful inspection reveals the presence of both uterine tubes and epididymal structures (Fig. 4.6).

Examination of the tubular structures from intersex animals commonly reveals the presence of both paramesonephric and mesonephric ducts (Fig. 4.7). In phenotypically female intersex animals, persistent mesonephric duct segments are most commonly found adjacent to, or opposed to, the lateral wall of the cranial segments of the uterus (paramesonephric ductal structure).

Freemartinism

Freemartinism occurs most commonly in cattle. The bovine freemartin is a genetic female born co-twin with a male (twinning occurs in 1–2% of pregnancies in cattle). The twinning is dizygotic in most cases; anastomoses develop between the placental vascular systems of the two fetuses (Fig. 4.8). Normal development of the gonads, tubular and external genitalia of the female embryo is dramatically altered by hormones and cells she receives through the common

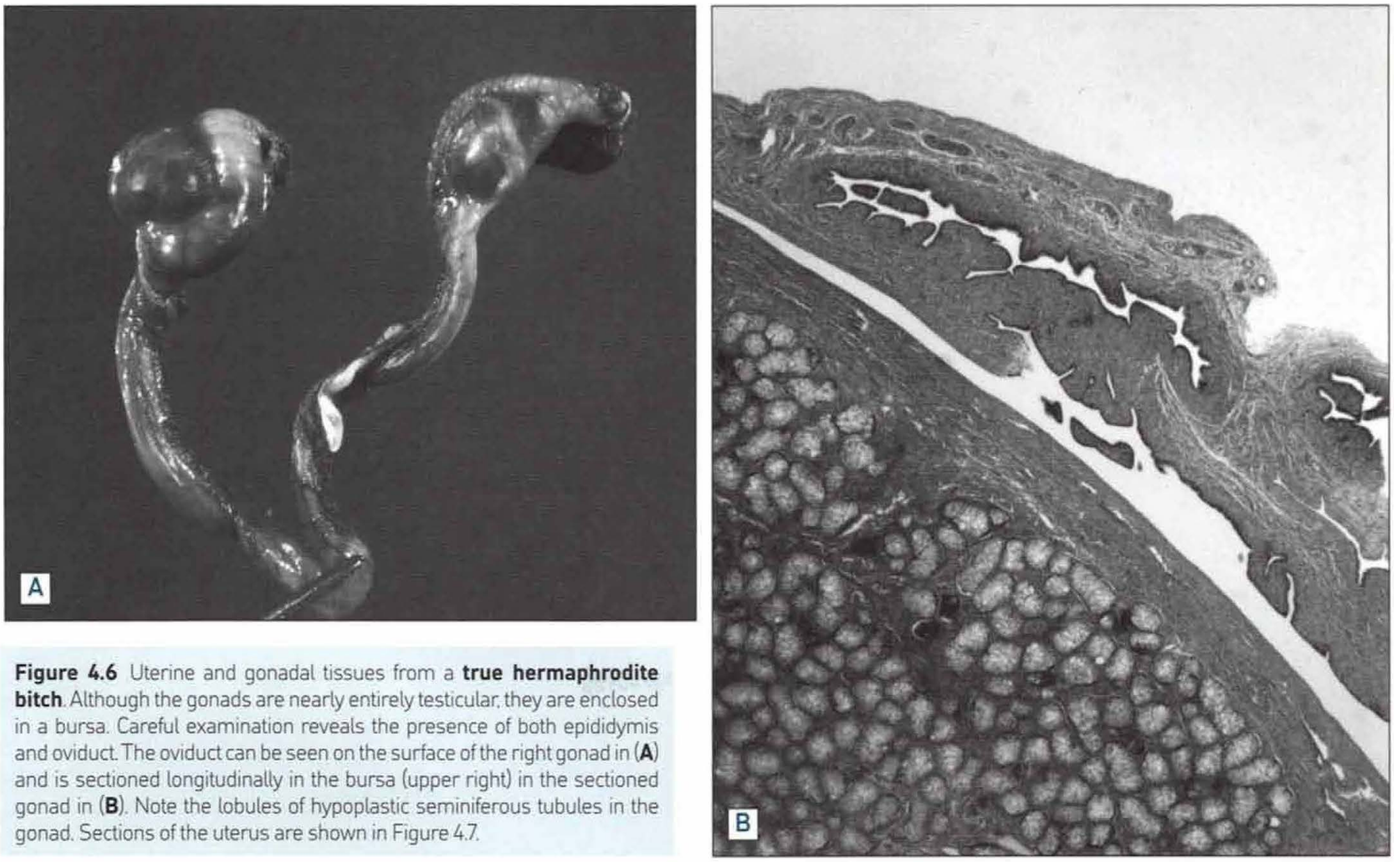

Figure 4.6 Uterine and gonadal tissues from a **true hermaphrodite bitch**. Although the gonads are nearly entirely testicular, they are enclosed in a bursa. Careful examination reveals the presence of both epididymis and oviduct. The oviduct can be seen on the surface of the right gonad in (**A**) and is sectioned longitudinally in the bursa (upper right) in the sectioned gonad in (**B**). Note the lobules of hypoplastic seminiferous tubules in the gonad. Sections of the uterus are shown in Figure 4.7.

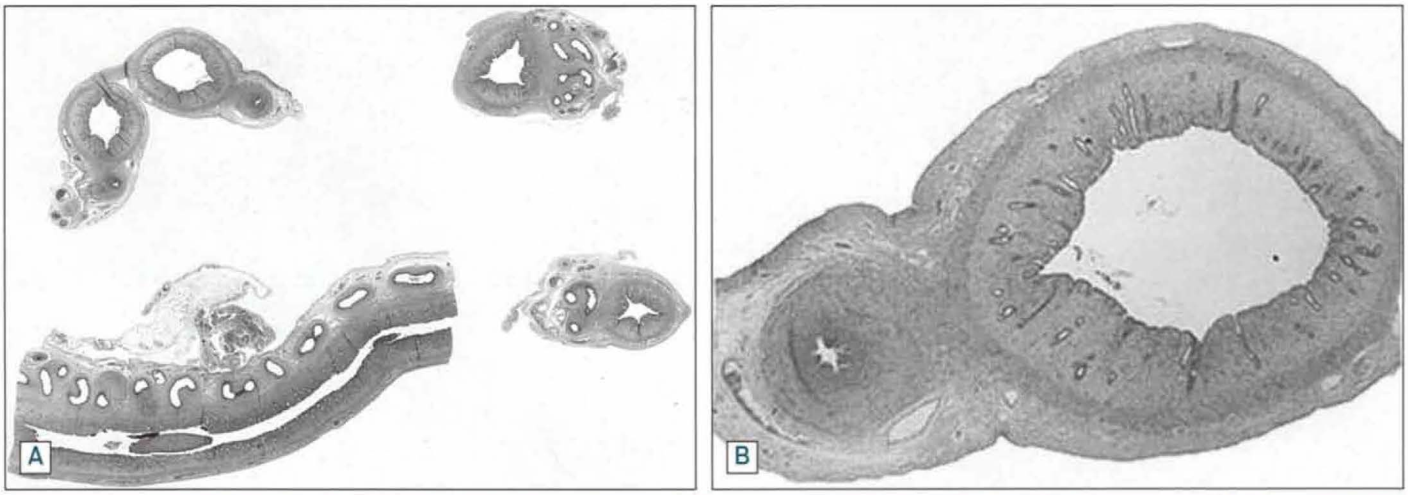

Figure 4.7 A, B. Subgross pictures of sections of the uterine horns from the **intersex bitch** in Figure 4.6. Note the presence of derivatives of both the **paramesonephric and mesonephric ductal systems** (uterine horn and vas deferens, respectively). The hypoplastic vas is present in both the cross-sections as smaller round structures at the point of attachment of the broad ligament (mesometrium) and in the longitudinal section (lower right), where it has been cut multiples times as it runs and bends along the uterine horn. Panel (**B**) is a high magnification of one of the uterine horns showing the small well-developed vas with its smooth-muscle wall and epithelial lining (smaller tubular structure on the left).

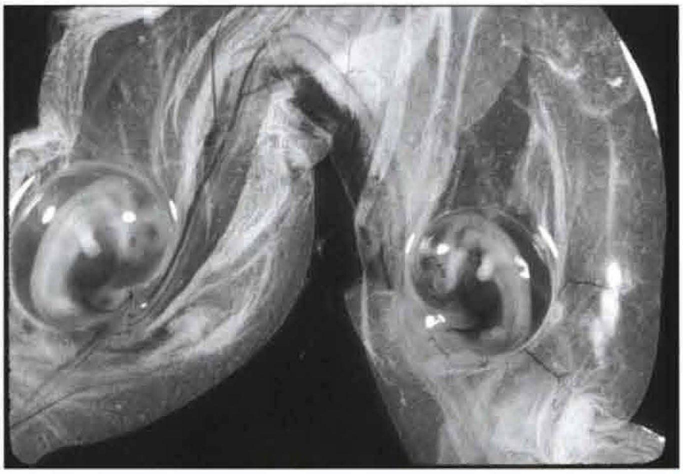

Figure 4.8 Twin bovine embryos contained within their amnions with fusion of branches of their umbilical arteries. Each embryo becomes a chimera and, if the twins are a male and a female, development of the female's reproductive organs will be masculinized; the constellation of changes that develop in her reproductive organs is known as the "freemartin condition."

circulation with her male twin. If anastomoses fail to develop, the female is not damaged, but *nearly all male–female twinning in cattle results in the female becoming a freemartin.*

The effect of the association on the male is always minimal. In the female, the gonads are stunted and frequently contain hypoplastic seminiferous tubules (ovotestes). The uterine horns are hypoplastic, or may be nearly completely absent or lack communication with the vagina (Fig. 4.9). Some parts of the mesonephric ductal system are commonly present. *A consistent feature (and therefore a key diagnostic feature) is the presence of poorly developed vesicular glands that are found attached to the lower fused segment of the paramesonephric ducts* (Fig. 4.10A). The vagina is short and nonpatent. The external genitalia commonly have enlargement of the clitoris, a small vulva, and a prominent tuft of hair (Fig. 4.10B).

Because of the clear association between freemartinism and the presence of interplacental anastomoses, and because the male gonads develop earlier than those of the female, it was presumed that male sex hormones were carried from the male fetus to the female, sterilizing and modifying the latter. The inadequacy of this explanation is demonstrated by the fact that androgens can masculinize a female fetus but they cannot inhibit the ovaries or the paramesonephric ducts. A critical observation was that *embryonic blood of the twins is*

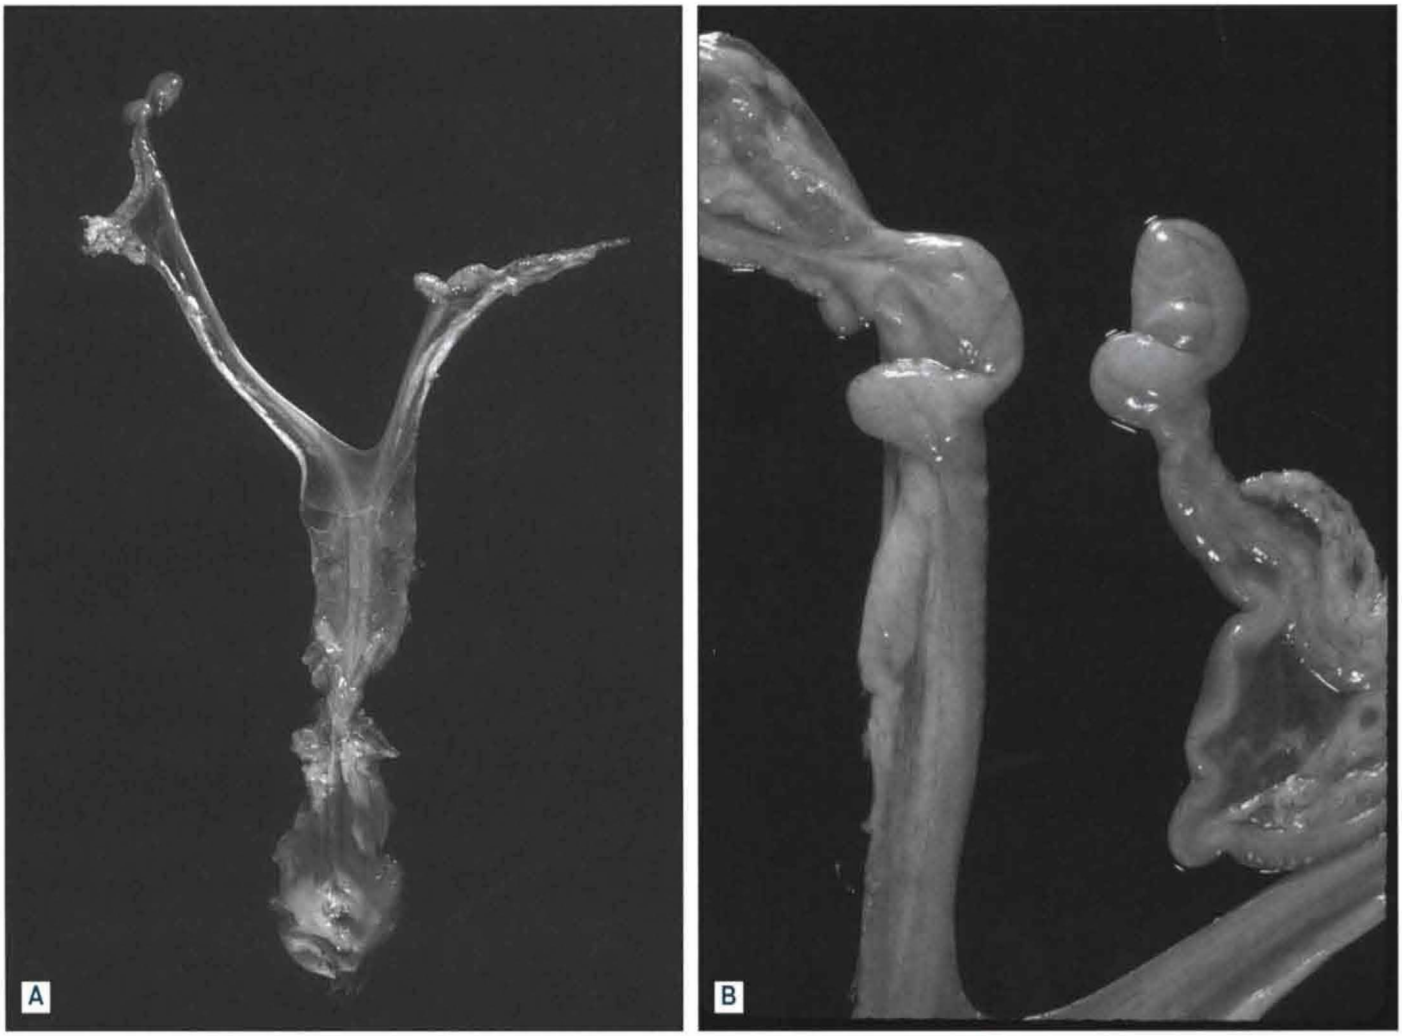

Figure 4.9 A. Reproductive organs of a **newborn bovine freemartin calf**. Note the markedly hypoplastic uterine horns, failure of the paramesonephric ducts to fuse to form a single uterine body, presence of paired seminal vesicular glands, and abnormal gonads. **B.** The gonads are ovotestes and are partially surrounded by epididymal tissues. A uterine tube is seen extending vertically below ovotestis on the right. (Therefore, derivatives of both the paramesonephric (uterine tube) and mesonephric (epididymis) ductal systems are present.)

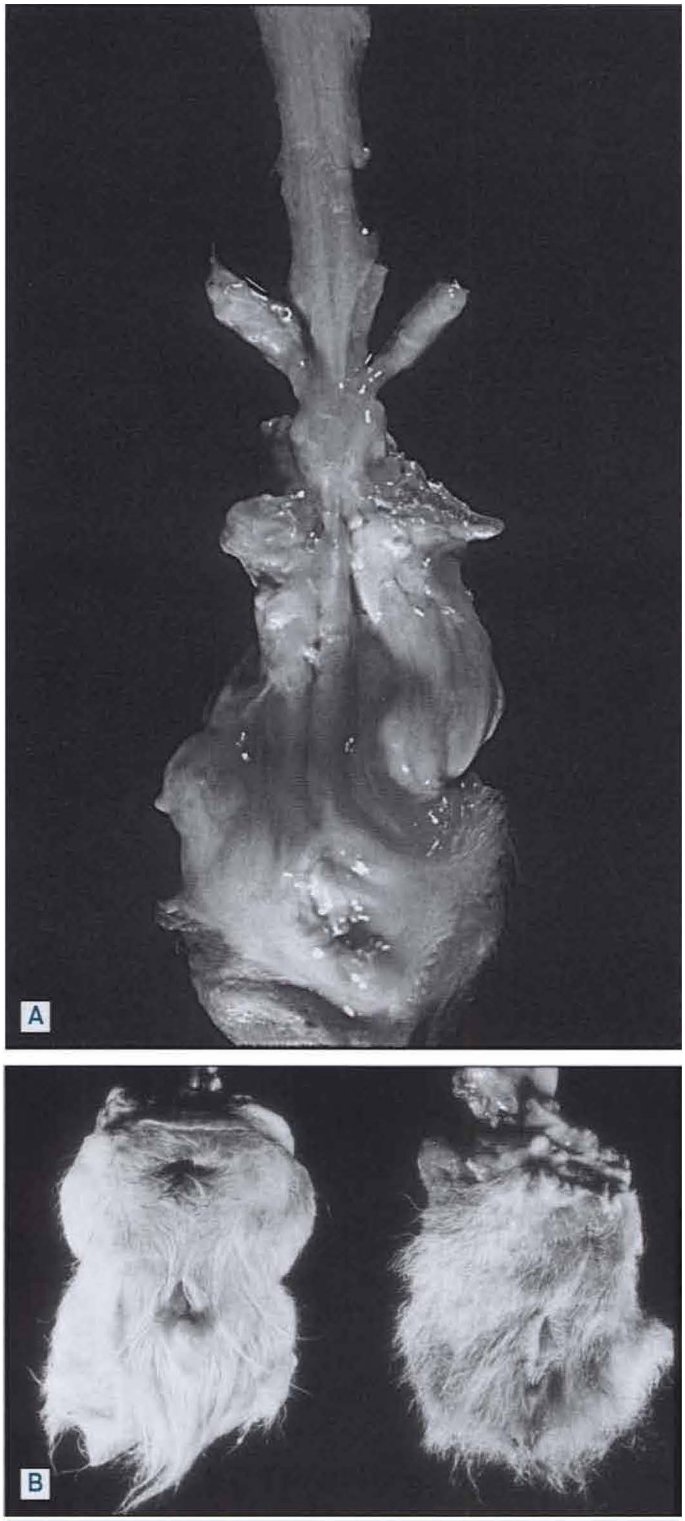

Figure 4.10 The caudal aspect of the tubular genitalia and vulva from the **freemartin heifer calf** in Figure 4.9. **A.** *A key diagnostic feature is the paired hypoplastic seminal vesicular glands* that consistently develop near the caudal segments of the paramesonephric ducts (which may or may not have fused). **B.** Comparison of the external genitalia of a normal newborn freemartin calf on the right and the prominent clitoris and a long tuft of hair attached ventrally to the freemartin calf's vulva on the left.

exchanged and leads to permanent colonization by hematopoietic cells, with the result that each twin develops an acquired tolerance for the blood cells of the other. This condition, known as **chimerism**, appears to be confined to hematopoietic cells. Although unproven, exchanges of nonhematopoietic cells do not appear to take place in freemartinism. *It is now believed that the male fetus sterilizes the female by the partial expression of testis-determining factor of the Y chromosome carried by the bloodstream via the placental anastomoses to the female gonad where it brings about ovarian inhibition.* This inhibition is manifest first functionally; estrogen production by the freemartin ovary is reduced and androstenedione is elevated as early as 40 days of gestation. This is well before morphologic evidence of damage can be recognized.

The gonad of a freemartin is usually a cord-like thickening in the cranial border of the ovarian ligament. Various degrees of modification of the gonad may occur. The rete is well developed, but other ovarian structures may be absent. Alternatively, greatly reduced ovarian tissue can be present but it lacks the normal germ cell complement. The morphologic variation shown in gonadal development is causally reflected in the variation of the tubular genitalia.

The epididymis is absent and the spermatic cord is poorly developed in cases with the lowest degree of male transformation. With increasing degrees of differentiation towards a testis, the spermatic cord and epididymis become better developed. The tubular genitalia, of paramesonephric duct origin, may vary from cord-like structures, without any lumina, to well-developed uterine horns with lumina and endometrial glands. *Communication with the vagina is always absent, no matter how well developed the uterus may be.*

Vestigial seminal vesicles are always present, the vagina is hypoplastic or nonpatent with a complete hymen, the vulva and vestibule are hypoplastic, and the clitoris is enlarged. Many freemartins have a prominent fold of skin on the median plane of the body, extending from a position ventral to the vulva to an area near the umbilicus. The mammary gland fails to undergo normal development.

The allantoic fusion in bovine twin pregnancies occurs at about the 10 mm stage of development. Approximately 90% of females born co-twin with males are freemartins and sterile. Freemartins occur in bovine triplets, quadruplets, and quintuplets as well as twins.

In *sheep*, dizygotic twinning is common and freemartinism does occur, but it is much less common; only 1% of heterosexual twins are freemartins in this species. The reason for this is the infrequency with which large-caliber interplacental anastomoses develop. Freemartinism does occur in *goats*, complete with blood chimerism, but is rare because, as in sheep, large anastomoses between fetuses are rare. Large anastomoses have been demonstrated between chorionic sacs in *swine* and freemartinism occurs in that species. However, because of the large litter size, it is difficult to identify the neighbor of intersex piglets, and the condition has not often been proven. Twin ovulation is relatively common in *horses*. Most twins do not survive to term, but vascular anastomoses with erythrocyte chimerism are frequent in equine twins, although freemartinism has not been convincingly demonstrated.

XX sex reversal

As described earlier, the female role in sexual differentiation is largely passive: the undifferentiated gonad will develop into an ovary unless the testis-determining factor is present, and the undifferentiated tubular genital tract will develop into normal female genitalia unless male hormones are present.

Testis induction during development is controlled by a master gene, the Y-linked *SRY* gene. There are, however, several syndromes of sex reversals in genetic females with XX karyotypes (referred to as XXSR). Much of what we know about these conditions we have learned from the condition in mice in which an autosomal dominant gene, *Sxr*, acts like a Y chromosome. Thus XX mice that carry the *Sxr* gene develop testes and male tubular genitalia. A somewhat similar condition has been observed in dogs, pigs, and goats, although in these species the autosome-associated gene with the Y action functions as a recessive gene.

Sex reversal caused by male differentiating genes on the X chromosomes of females has been reported in over 15 breeds of *dogs*. For some time, this condition has been recognized in the American Cocker Spaniel breed, in which XX phenotypic males and XX true hermaphrodites have been described. Some of the true hermaphrodites have functional ovarian tissue and have given birth to pups, but testicular tissue present in the gonads of either the XX males or the XX true hermaphrodites has invariably lacked germ cells. The condition is inherited as an autosomal recessive. Recent work has shown that XXSR dogs are *SRY*-negative, and has implicated other genes, possible *SOX9*, as being responsible for initiating male differentiation in XX female canine embryos.

The condition has also been studied in *goats* in which the autosomal gene with the Y effect is on the chromosome that controls polling or is closely linked to it. The polled gene is a dominant autosome, a single copy of which produces hornlessness without affecting sex differentiation. In the homozygous condition, however, XX goats are rendered hermaphrodites. They have testes or ovotestes. It has been presumed that the translocation of a subcritical portion of the testis-determining gene to the autosome that contains the gene for polling has produced the recessive mode of sex determination. There is a considerable range of masculinization. The affected individuals may have largely female appearance with only an enlarged clitoris and abdominal testes. Other animals have the appearance of near-normal, although sterile, males.

Sex reversal is common in *pigs*. The mode of inheritance is not well understood, and some cases may have been confused with freemartinism. The masculinizing effect is incomplete. The gonads in

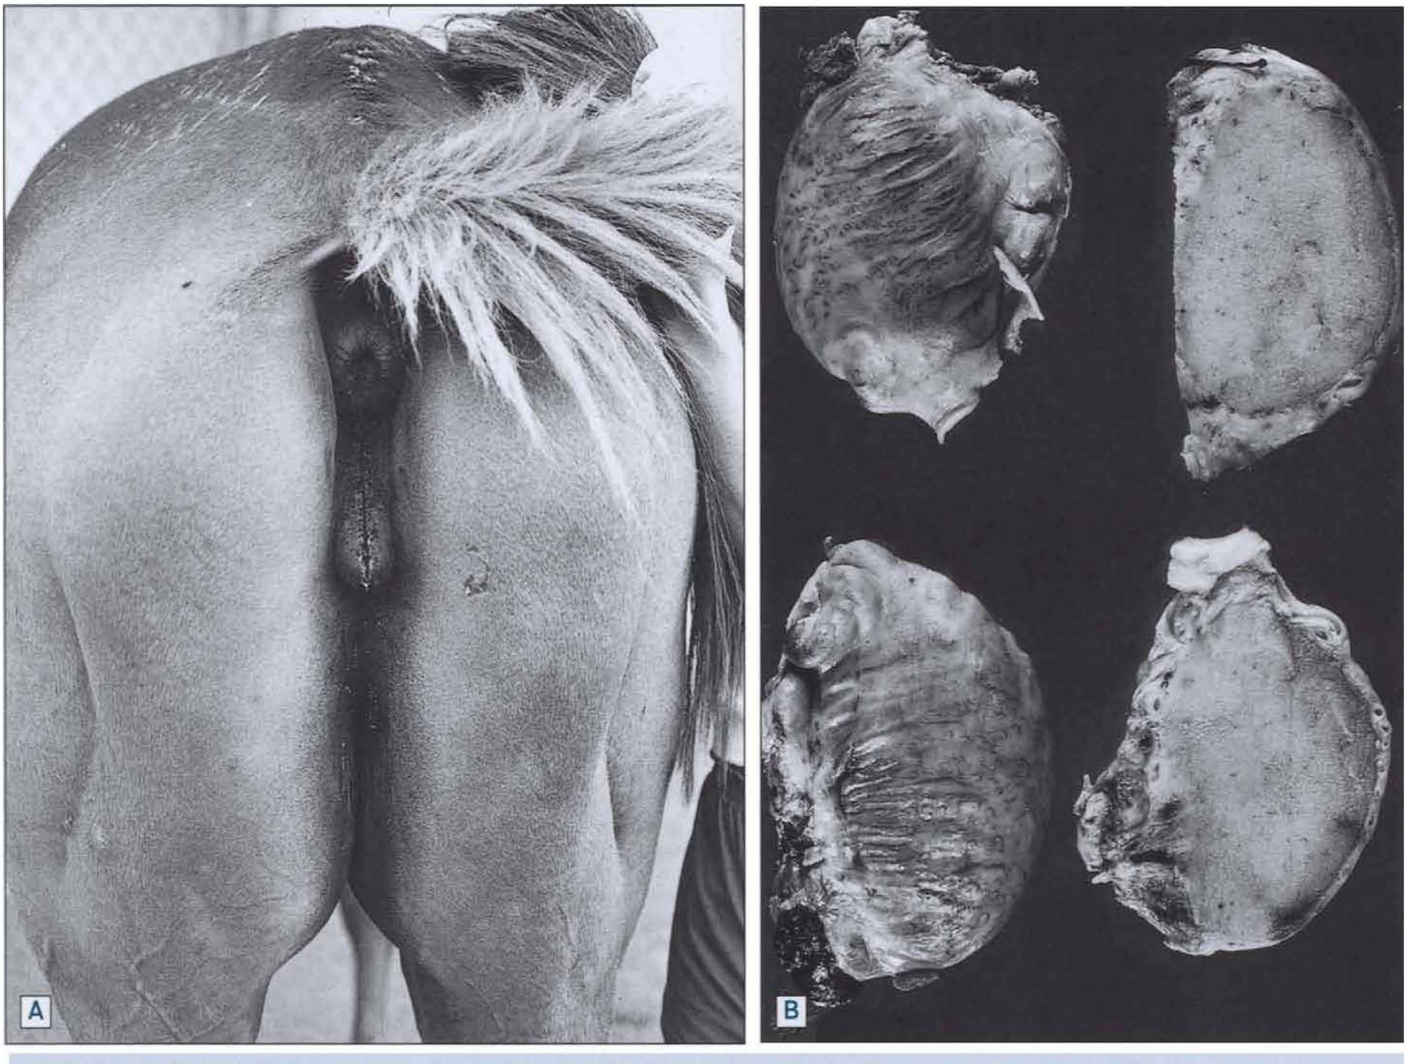

Figure 4.11 A. Androgen insensitivity (testicular feminization) in a mare. The external genitalia appear as a normal mare, but the genetic sex of this animal is male and the gonads are testicular (intra-abdominal, hypoplastic), as shown in panel **B.** The tissues of the external genitalia lack androgen receptors. Even though the genetic and gonadal sex is male and the fetal gonads produce testosterone and the appropriate enzyme systems for conversion of testosterone to dihydrotestosterone, the absence of receptors for dihydrotestosterone in the developing external genital tissues leads to failure of masculinization.

affected individuals are often ovotestes and, although the testicular tissue lacks germ cells, ovulation and pregnancy have been reported. This condition can be distinguished from freemartinism by demonstrating that blood chimerism does not exist in affected individuals.

XY sex reversal in the mare

Individual examples of domestic animals that had XY karyotypes but were phenotypically female have been reported. In the horse, an inherited XY sex-reversal syndrome has been identified. Pedigree analysis suggests that the trait is inherited as the result of an autosomal sex-limited dominant gene or as a Y chromosomal mutation with variable expression. There is a considerable range of phenotypic expression in this syndrome. Affected individuals vary from phenotypically normal but sterile mares with inactive ovaries and normal tubular genitalia to individuals with streak gonads or ovotestes and severely hypoplastic or aplastic tubular genitalia.

Androgen insensitivity

A syndrome of androgen insensitivity has been recognized in humans, mice, rats, cats, cattle, and horses. This inherited syndrome is most often called *testicular feminization* and the *controlling mutation identified as Tfm*. Affected individuals are of XY genotype and have testosterone-producing testes. The external genitalia are female in type. The *Tfm* mutation produces a deficiency of intracellular androgen receptors, rendering all cells insensitive to androgens. MIS is still produced by the testes of affected animals, and therefore paramesonephric duct derivatives are absent because of their sensitivity to this hormone.

Equine male pseudohermaphrodites of this syndrome have normal-appearing female external genitalia (Fig. 4.11A). The vagina ends in a blind sac, with no cervix, uterus, or fallopian tubes being present. The gonads are small and clearly testicular, but present in the normal ovarian position (Fig. 4.11B).

The seminiferous tubules are small and lined by inactive Sertoli cells (Fig. 4.12A). Rare spermatogonia can be found, but spermatogenesis does not occur. Well-differentiated Leydig cells are closely applied to the seminiferous tubules (Fig. 4.12B).

Horses with the syndrome have no detectable male accessory sex glands. The cattle that have been described have rudimentary seminal vesicles and ampullae. Both cattle and horses that lack androgen receptors have normally formed female mammary glands. Horses are unique among the species in which the syndrome has been

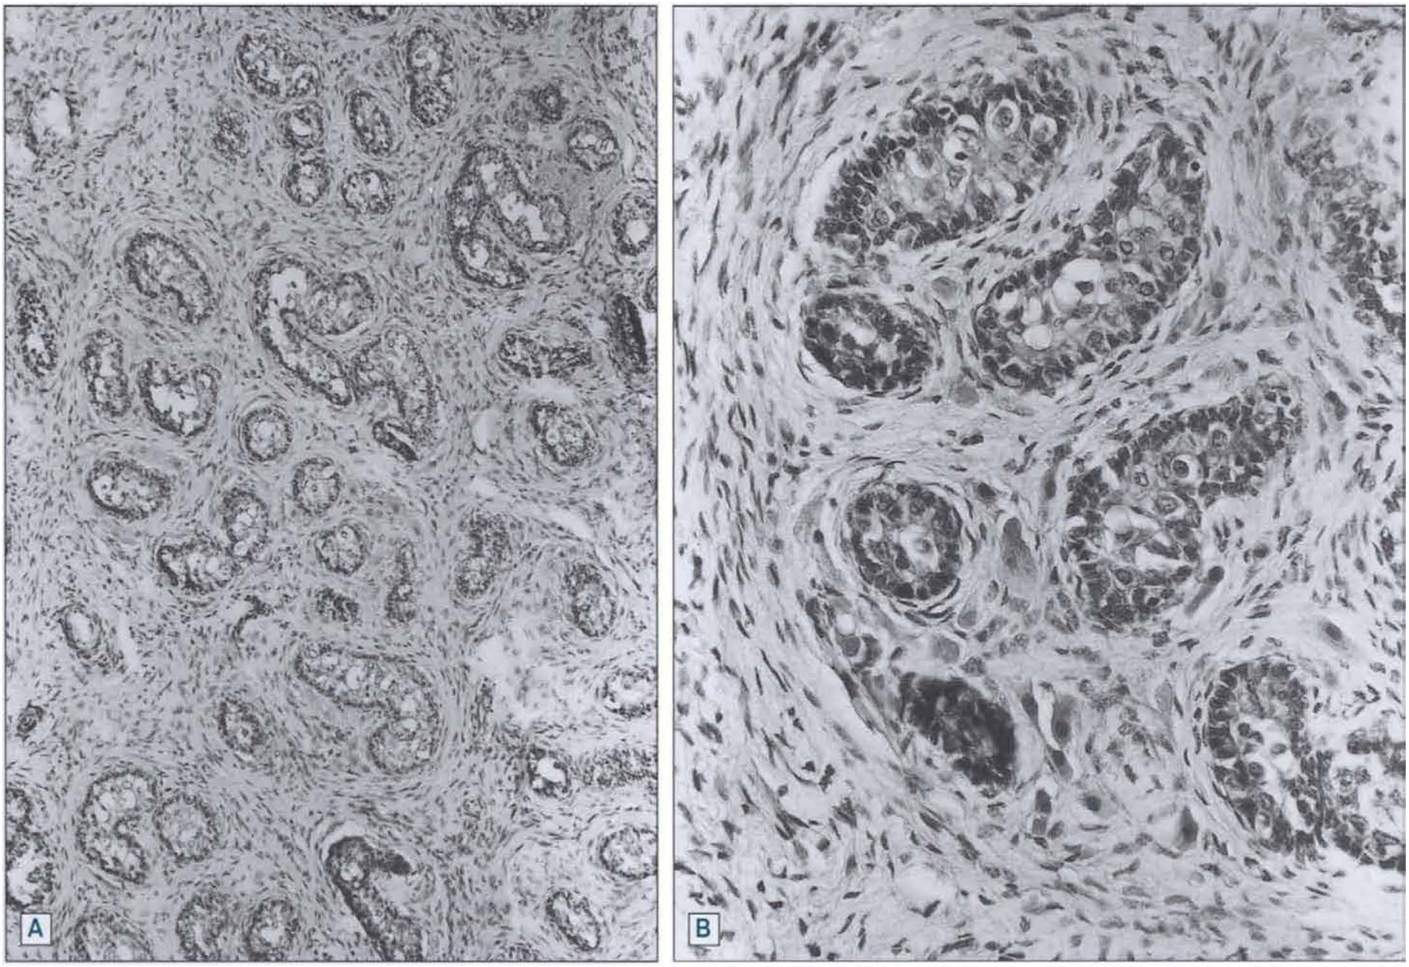

Figure 4.12 A. Photomicrograph of tissues from the **intra-abdominal testicle** from the mare in Figure 4.11 demonstrating the presence of many interstitial cells in the stroma separating hypoplastic seminiferous tubules. The interstitial cells produce testosterone that is converted to dihydrotestosterone, which causes the phenotypic masculinization in those tissues containing the appropriate receptors. **B.** Higher magnification of hypoplastic seminiferous tubules.

reported in that affected individuals show male behavior patterns. This syndrome of male pseudohermaphroditism can be distinguished from others by assaying the cytosol receptors of the androgen target cells. This can be done most conveniently by culturing fibroblasts from the genital skin. It is important that labial tissue be used, because receptor activity is sharply reduced in nongenital skin.

Ovary – developmental anomalies

Agenesis of one or both ovaries is rare, but has been observed in ruminants, swine, and dogs. In bilateral agenesis, the tubular genitalia may be absent as part of the defect or, if present, are infantile or underdeveloped.

Duplication of ovarian tissues is very rare. Although there are no controlled studies, duplication may in reality be splitting of ovarian gonadal tissue. Ovaries from a young calf with ovarian duplication are shown in Figure 4.13.

Ovarian remnants: interest in the occurrence of anomalous ovarian duplication commonly arises when either cats or dogs, supposedly surgically neutered, exhibit signs of estrus. This is referred to as the *ovarian remnant syndrome.* In the bitch, the effects of circulating estrogen can be relatively easily detected by doing serial vaginal cytology. Ultrasonographic and exploratory examinations are done when the animal is in estrus and has large follicles, or during the luteal phase of the cycle, when corpora lutea would also make ovarian tissue easily identified. Although occasionally proposed, there is little information concerning whether small pieces of ovarian tissue inadvertently released during canine or feline surgery might be able to implant on the peritoneal surface in the abdomen.

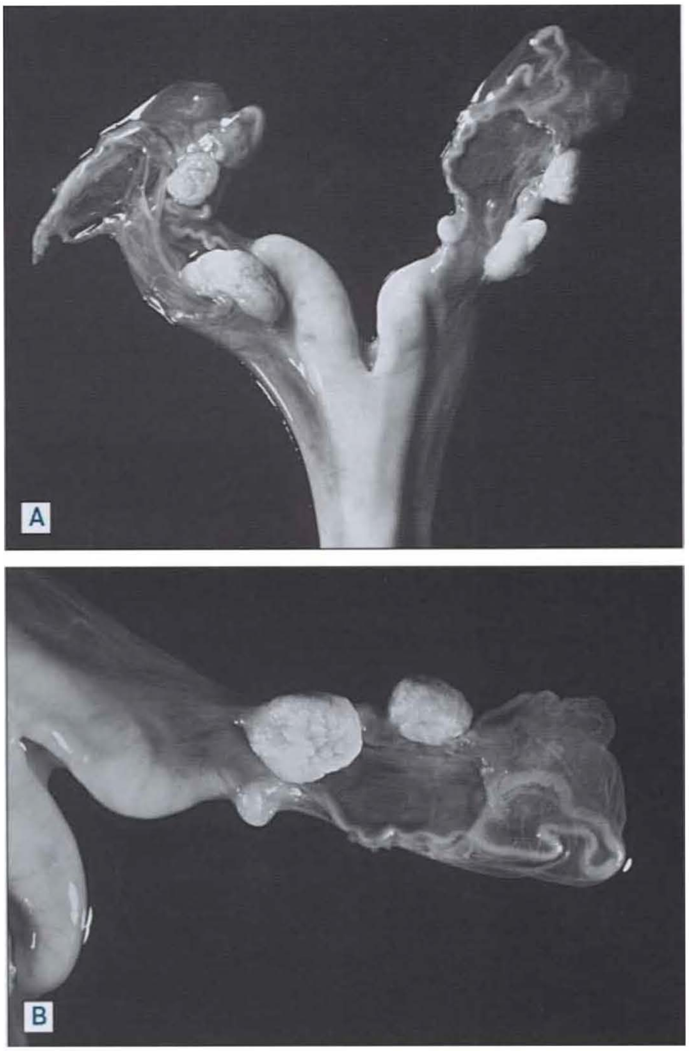

Figure 4.13 A. Duplication of the ovaries occurs very rarely. The gonads in this newborn calf were each divided, giving the impression that two separate gonads had formed. An isthmus attaches the pair of ovaries. **B.** The two pieces of the left gonad are more clearly shown.

Vascular hamartomas of the ovary have been described in swine and cattle. Since they are often confused with neoplasms, they are described in the section on ovarian tumors (see p. 456).

Hypoplasia of the ovaries has been studied primarily in cattle, but occurs in other species. *It is usually bilateral but varies considerably in its severity and symmetry,* so that "severe hypoplasia" or "partial hypoplasia" may be applicable to one or both ovaries. In severe hypoplasia, the defective gonad varies in size from a cord-like thickening in the anterior border of the mesovarium to a flat, smooth, firm, bean-shaped structure in the normal position. There are neither follicles nor luteal scars and, microscopically, the ovary is largely composed of medullary connective tissues and blood vessels.

Ectopic adrenal tissue is usually found incidentally during histopathology. These small nodules are composed of adrenal cortex and are most commonly found on the surface of the ovary of mares or adjacent to the ovary of queens (Fig. 4.14).

Cysts arising from remnants of developmental structures

Cystic lesions in and near the ovary and uterine tubes are common, especially in the mare. Figure 4.15 demonstrates the embryonic origin of the most common of these cysts.

Cysts arising from either the cranial or caudal segments of the mesonephric tubules are found as thin-walled, movable cysts at either the cranial or caudal pole of the ovary and are called **cystic epoophoron or paroophoron**, respectively. Cystic epoophorons are more common and can become quite large, especially in the mare (Fig. 4.16), and are discussed below. **Cystic rete** are common

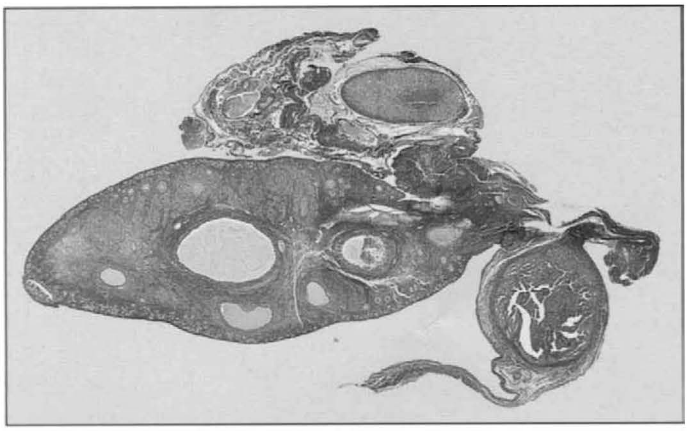

Figure 4.14 Ectopic adrenal tissue is most commonly found adjacent to, or attached to, the tunic of the ovary of the queen and mare. A nodule of ectopic adrenal tissue (upper right) is evident adjacent to the ovary and uterine tube in this subgross photograph of tissues from a queen.

in the cat and dog, and arise from the rete ovarii, which are also derived from the mesonephric tubules. These arise in the hilar area of the ovary. All derivatives of the mesonephric tubules commonly have variably prominent smooth muscle in their walls. The epithelial lining is cuboidal in small cysts, tends to become squamous in slightly larger cysts, and is usually absent due to pressure atrophy in larger cysts. Only the cystic rete commonly progress to compress ovarian tissues to such a degree as to compromise ovarian function. Adenomatous hyperplasia of the rete epithelium is common, and cystic adenomas occur, most commonly in the bitch.

By far the most common type of cyst arising from remnants of the embryonic ducts or tubules is found in fillies and mares. These are *cystic apical segments of the paramesonephric duct*. These are also called **fimbrial cysts** and appear as one or two thin-walled cysts, up to 1 cm in diameter, that are attached to the fimbria of the uterine tube (Fig. 4.17). Careful examination of the fimbria during necropsy will reveal that these are very common. During clinical examinations, they may be detected by palpation or by ultrasonography, but do not reduce fertility. The differential diagnosis is a cystic remnant of the mesonephric duct, but these are found adjacent to the uterine tube or along the lateral border of the uterine tube, uterine body, or in the cervix or vagina.

Mesonephric duct remnants are frequently found as small cysts lying along the lateral side of the uterine tubes, uterine horns, uterine body, cervix, or cranial vagina. They are in or near the attachment of the mesosalpinx or mesometrium of the uterine tube and uterine horns, but those found in the uterine body and cervix tend to be found within the myometrium, and those in the vagina are commonly multiple or linear cystic structures in the submucosa. Intersex animals with a predominantly female phenotype often have remnants of persisting segments of mesonephric ducts that are located in the attachment of the broad ligament and run parallel with the uterine horns (Fig. 4.18). These cystic remnants of the mesonephric duct have the microscopic appearance of the vas deferens and have

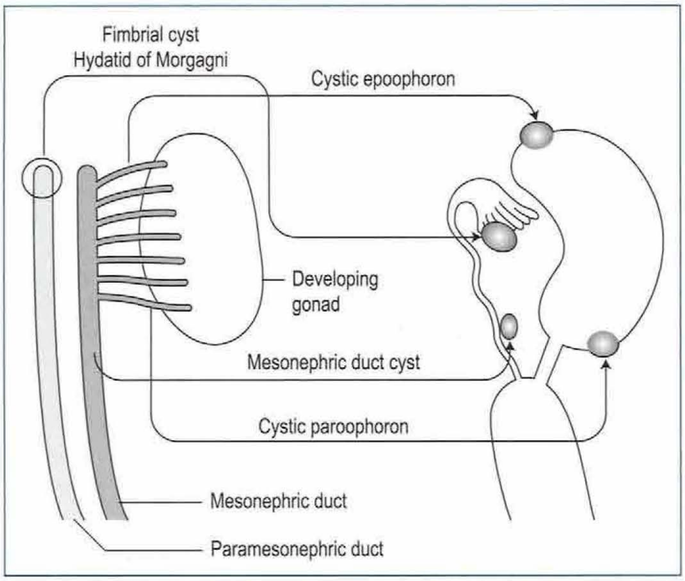

Figure 4.15 Cysts in or near the ovary and along the uterus are common, but usually incidental findings. The embryonic origin of several common cysts is shown in this drawing. Details are provided in the text and examples of some of these cysts as they occur in different species are shown in the following figures. (Illustration by Michael Simmon.)

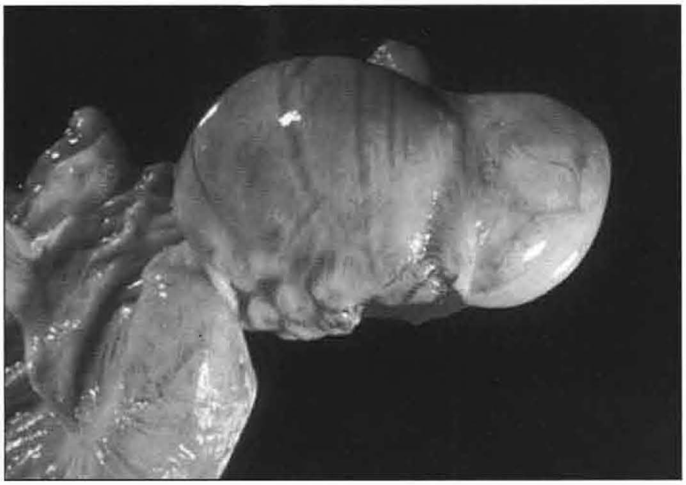

Figure 4.16 A large **cystic epoophoron** extends from the proximal pole of the ovary of a mare. These cysts arise from remnants of the cranial mesonephric tubules, and although they can become large, do not reduce fertility. They are palpable per rectum and can be seen during ovarian ultrasonography.

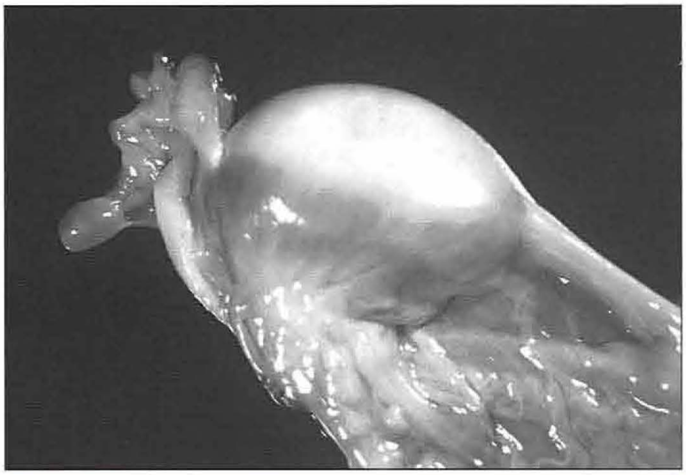

Figure 4.17 Paramesonephric duct cyst (fimbrial cyst) extending from the fimbria of the uterine tube of a young filly.

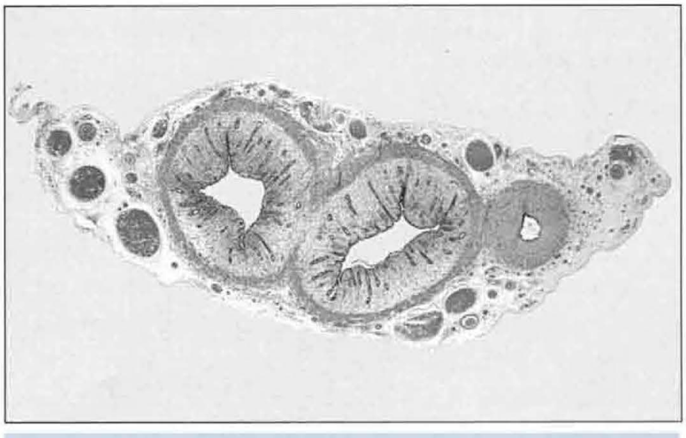

Figure 4.18 Cross-section of two uterine horns and **unilaterally persistent mesonephric duct** (right side) from an intersex bitch. These remnants occur as either cysts or short segments of hypoplastic vas deferens.

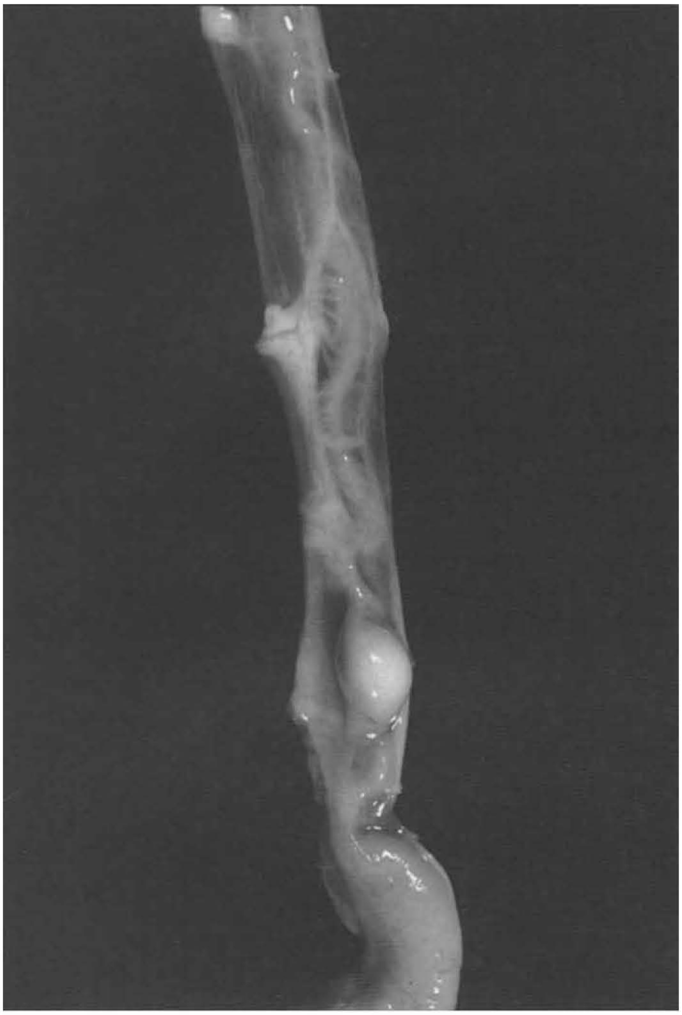

Figure 4.19 Cystic remnant of a mesonephric duct adjacent to the uterine tube from a cow.

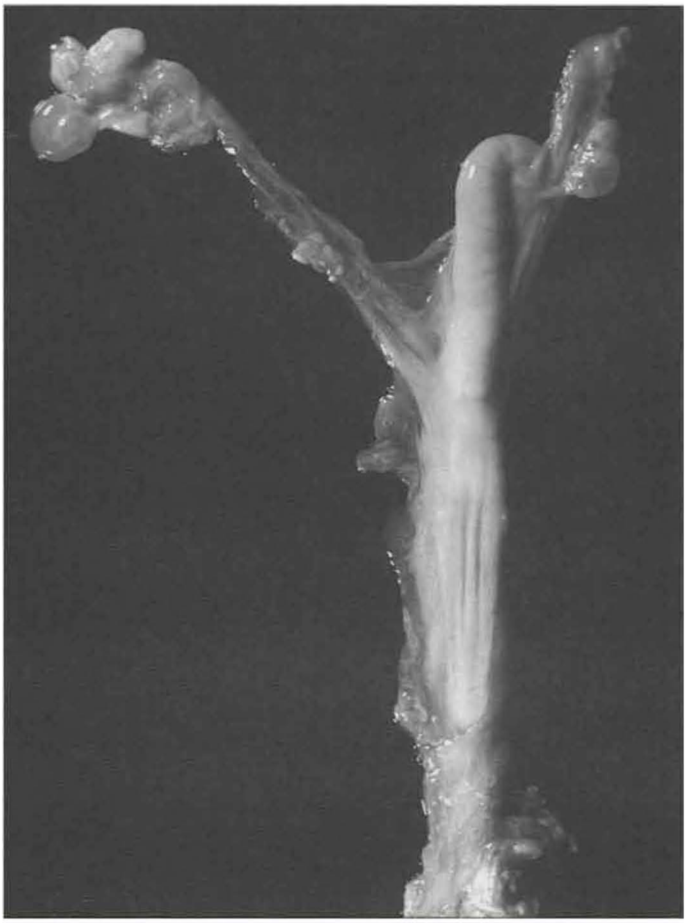

Figure 4.20 Segmental aplasia of the left uterine horn of a heifer caused by failure of a segment of the paramesonephric duct of this side to develop normally. Also note the hydrosalpinx.

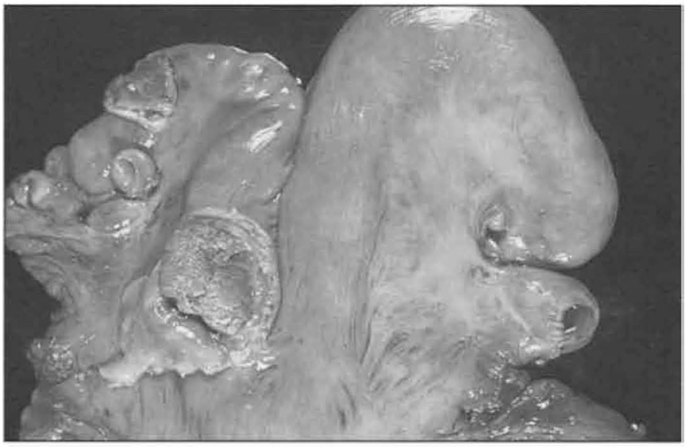

Figure 4.21 Segmental aplasia of the left uterine horn of an adult cow opened to demonstrate soft tan **concretions** formed from accumulated uterine secretions and sloughed cells.

a lumen lined by epithelial cells and a relatively prominent small muscle wall.

Cystic mesonephric duct remnants are common in the cow. The fluid they contain is usually clear, but may be opaque (Fig. 4.19).

Arrests in the development of the paramesonephric ductal system

There are three patterns of defect:

1. failure of segments of the paramesonephric ducts to develop,
2. failure of the caudal parts of the two paramesonephric ducts to fuse appropriately and develop a single lumen,
3. failure of the caudal ends to the fused paramesonephric ducts to fuse with the invaginated urogenital sinus, leading to failure of the lumen of the fused ducts to become continuous with the caudal vagina.

Segmental aplasia of the paramesonephric duct system is found as either failure of short or long segments of the uterine horn to develop (Fig. 4.20). This was commonly found in white Shorthorn cattle and gave rise to the name "white heifer disease" for the syndrome, but no breed is exempt from the condition. The arrested development is thought to be autosomal recessive. Complete absence of an entire horn is referred to as **uterus unicornis**.

Within the isolated segments of uterus, secretions and sloughed epithelial cells become inspissated and often form soft tan concretions within the distended isolated lumen of the uterine horn proximal to the area of segmental aplasia (Fig. 4.21).

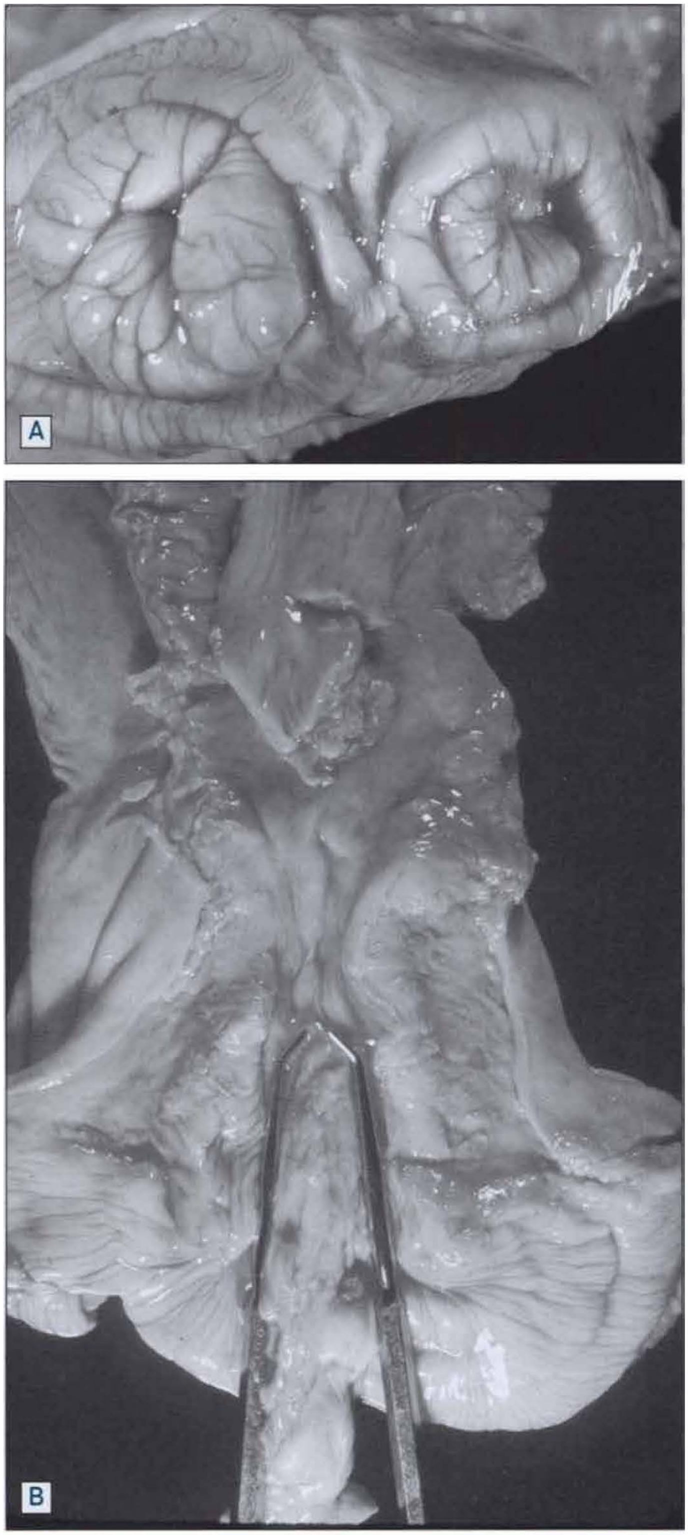

Figure 4.22 **A. Double cervical os** (as viewed from the vagina) caused by failure of the mesonephric ducts that normally join and fuse during embryonic development to do so. **B.** The defect as demonstrated in the opened uterus and cervix in (**B**) is common. A single lumen in the uterine body (normal: formed by fusion of the two paramesonephric ducts) and two separate cervical lumens (demonstrated by the probes placed in the two cervical lumens) are seen in the most common form of this defect in cattle. Complete division of both the uterine body and cervix is less common and is called *uterus didelphus*.

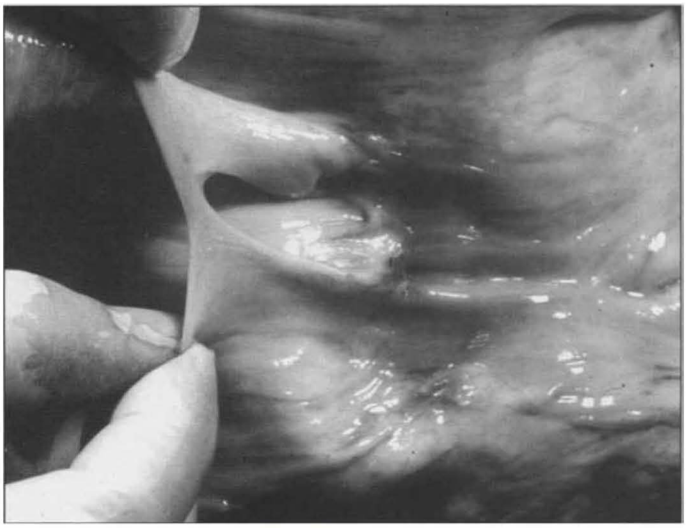

Figure 4.23 **Incomplete hymen** in a young heifer. The hymen is a persistent membrane of tissue that was formed by the inward expansion of the urogenital sinus on one side (forming the vagina) and the caudal development of the joined paramesonephric ducts on the other. Complete or partial hymen is commonly found in young calves, and occasionally in young females of other species. They are usually torn during breeding or parturition, usually presenting no clinical problems.

Failure of the paramesonephric ducts to fuse is most commonly found in the cow and usually involves the cervix, and less commonly the uterine body. Partial failure of the paramesonephric ducts to fuse with loss of the joining wall to form a single lumen is more common than complete failure to fuse. An example of the more common appearance is shown in the tissues in Figure 4.22. The uterine body and cranial cervix have developed normally, but there is a median septum in the cervix, leaving two cervical canals and the appearance of two cervices. The apparent septum is the medial walls of the two paramesonephric ducts that failed to regress.

Less commonly, there may be failure of the caudal aspects of the paramesonephric ducts to fuse. This occurs on occasion in the bitch and results in the presence of a longitudinal median band of tissue extending from the mid dorsal to the mid ventral walls of the vagina cranial to the urethral orifice.

Failure of fusion of the paramesonephric ducts with the urogenital sinus results in persistence of a tissue band running across the vagina just cranial to the opening of the urethra. This tissue forms an **imperforate hymen** that can either be complete, or more commonly is only a small piece of the wall (Fig. 4.23). In association with imperforate hymen, the remainder of the genital tract may be normal, but if the hymen is complete, in time and with the accumulation of secretions (there may be 10 liters or more), the vagina, cervix, and uterus become distended and atonic. If the hymen is perforated and the distension relieved early, the genital tract may function normally, but prolonged and severe dilation leads to atrophy and permanent loss of tone of the walls. Bacteria may be fortuitously implanted in the uterine contents to produce pyometra.

Moderate **hypoplasia of the cervix**, in which some rugae are absent and the canal widely patent, may militate against functional closure of the canal and predispose to persistent invasion of the uterus by microbes, and chronic endometritis. Occasionally, the cervical canal is irregular in its course or even tortuous. Although

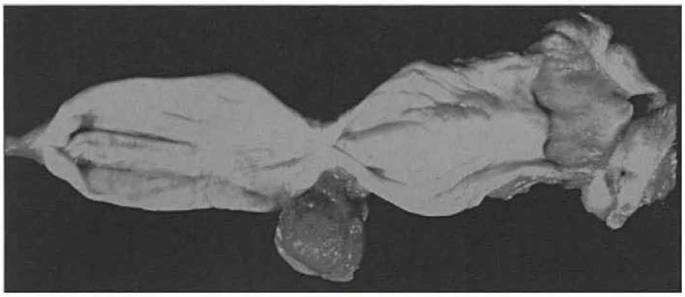

Figure 4.24 Segmental stenosis of the tubular genitalia is uncommon in dogs or cats. The middle region of the vagina of this bitch was completely occluded and the lumen of the cranial vagina was distended with tan fluids.

this may not interfere with conception following natural breeding, insertion of an inseminating catheter may be difficult or impossible. Repeated attempts to pass a pipette can lead to cervical trauma, occasionally complicated by formation of traumatic inclusion cysts or abscesses.

Dilations and diverticula of the cervix have been observed as a cause of infertility in heifers. The malformations occur at the level of the third and fourth rugae, and the cervical canal is usually constricted caudal to the defect. The dilated areas are usually spherical and located near the internal os. Diverticula are dorsal or dorsolateral and eventually become filled with tenacious mucus. The cause of the condition has not been established, but it is assumed to be developmental.

Vaginal anomalies

Vaginal stenosis is uncommon and may be either congenital or acquired. The stenosis in Figure 4.24 was complete and had caused dilation of the proximal vagina.

PATHOLOGY OF THE OVARY (NONDEVELOPMENTAL LESIONS)

Reproductive organs of sexually mature animals normally undergo dramatic changes during the estrous cycle. These morphological changes associated with follicular development, ovulation, luteinization, and regression of the corpus luteum are referred to as the **ovarian cycle**. Species variations exist that can potentially be very confusing, both during gross and microscopic examination. Albeit beyond the scope of this chapter, the importance of acquiring basic information from the relevant literature, including basic texts on animal reproduction and theriogenology, cannot be overemphasized.

Miscellaneous lesions

Intrafollicular hemorrhage occurs commonly in calves and is also found in follicular cysts in the bitch, and occasionally in atretic follicles of cows. Hemorrhage occurs during ovulation in all species of domestic animals, but is usually minimal and largely confined to the cavity of the collapsed follicle. However, it can be severe and occasionally even lethal in the mare. In the mare in the autumn at the beginning of the period of seasonal anestrus, hemorrhage occurs into anovulatory follicles ("autumn follicles").

Focal areas of serositis develop adjacent to corpora lutea, indicating that they occur following ovulation. The recently formed strands of tissue, which are referred to as **ovulation tags**, are composed of fibrin, proliferating capillaries, and leukocytes. As the lesion regresses, neutrophils are replaced by lymphocytes, macrophages, and plasma cells, and mesothelial cells cover the tags. Fine bursal adhesions may result, but they are too delicate to interfere with ovulation or the passage of ova into the oviduct. Ovulation tags occur in all species, but most frequently in the cow and mare. Scars that form on the surface of the ovary are small and of no consequence.

A significant form of **ovarian hemorrhage** is that which follows the older clinical practice of manual enucleation of corpora lutea in cattle. The blood loss may vary from 0.5 liters to several liters and cause death. Hemorrhage is more profuse in pregnant cows and those with pyometra than in normal cycling cattle. In cases of pyometra and salpingitis, the release of inflammatory detritus into the bursa often results in the formation of extensive adhesions between the oviduct and ovary. The expressed mass of luteal tissue persists indefinitely as a roughly spherical, flattened soft mass. The mass develops a fibrous capsule enclosing the necrotic luteal cells and can be differentiated from a lipoma.

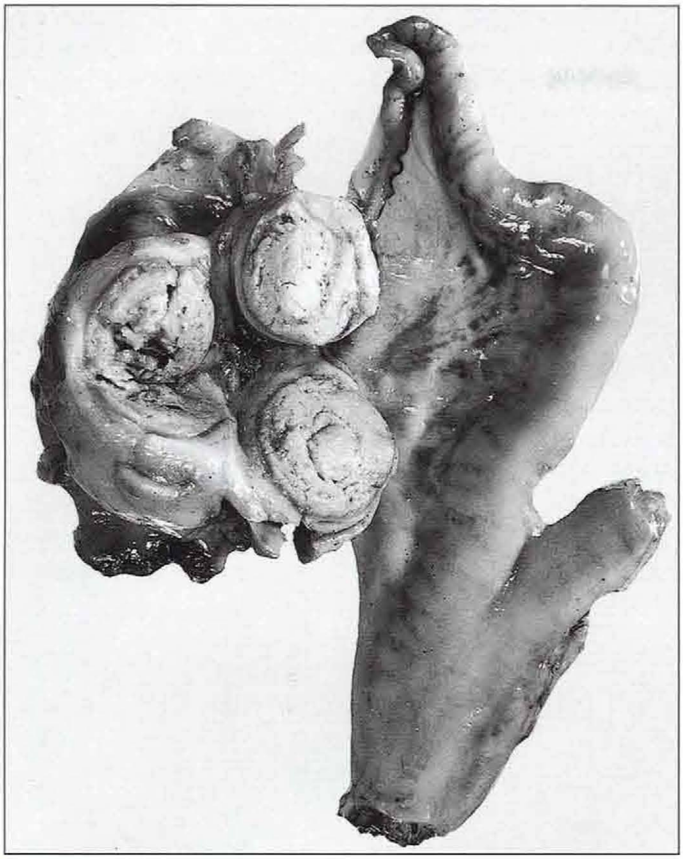

Figure 4.25 Caseous oophoritis caused by *Corynebacterium pseudotuberculosis* in a ewe.

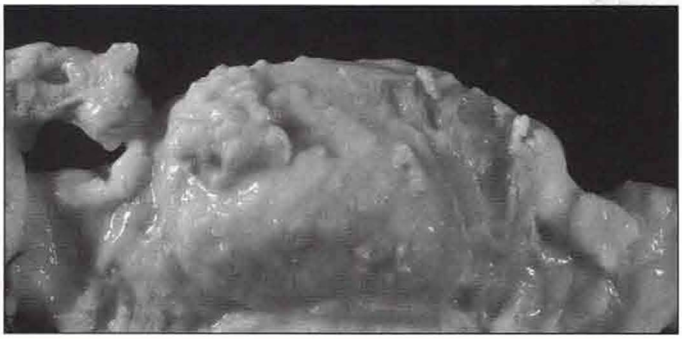

Figure 4.26 Purulent oophoritis nearly completely destroying the ovary of a cow. The cow also had suppurative salpingitis and metritis.

Postparturient vascular lesions occur frequently in the bovine ovary. The changes consist of intimal proliferation of mucoid tissue in ovarian arteries and hyalinization of the walls of arteries and arterioles. Some of the more severely affected vessels occasionally undergo thrombosis. Degeneration of arterioles also occurs in rapidly regressing corpora lutea associated with abnormally short estrous cycles.

Oophoritis is relatively rare and, when it occurs, it is usually pyogenic (Fig. 4.25).

Abscessation of the ovary may follow enucleation of the corpus luteum in cows with pyometra or from oocyte retrieval using needle aspiration (Fig. 4.26). Serosal granulomas on the ovary occur in bovine peritoneal tuberculosis and in brucellosis, visible macroscopically as small red nodules or tags. Similar lesions are usually visible on adjacent serosal surfaces of the genital organs and adnexa. These infective granulomas remain localized to the surface of the ovary and do not penetrate its substance.

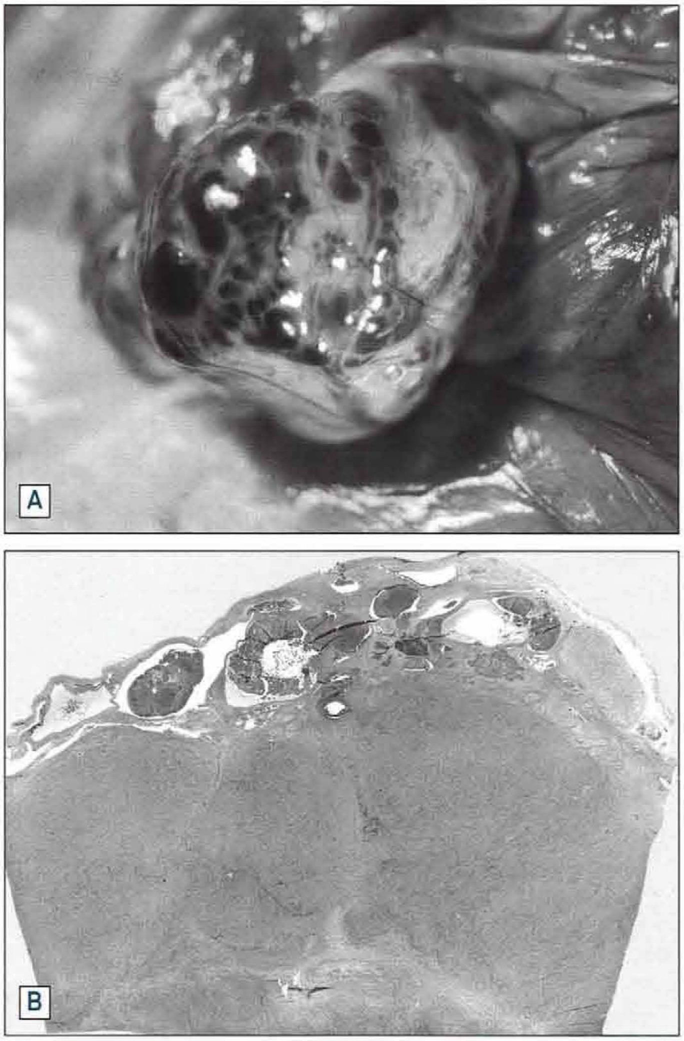

Figure 4.27 A. Varicose veins on the surface of the ovary of an older mare. **B.** Subgross photograph showing distended veins on the surface of this ovary.

Age-related degenerative changes

Equine ovarian varicosities

The surface of the equine ovary is richly endowed with veins that, with age, commonly become varicose. Thrombi may form, and if extensive can lead to infarction, or ischemic damage to the ovary. Ovarian varicosities do not usually occur in other species. They appear as dark, nearly black serpentine fluid-filled tissue on the surface of the ovary (Fig. 4.27).

Ovarian cysts

Cysts arise either within, or adjacent to the ovary. Several cysts that develop from embryonic structures, the mesonephric duct, mesonephric tubules, and paramesonephric duct, were discussed above where an illustration (see Fig. 4.15) was used to summarize the embryonic structures from which some common cysts arise. These cysts will be briefly discussed in this section.

There are three types of **cysts that develop from mesonephric tubules**: cystic rete, cystic epoophoron, and cystic paroophoron. **Cystic epoophoron** (see Fig 4.16) develops from the cranial mesonephric tubules, whereas **cystic paroophoron** occurs less commonly and is found on the caudal surface of the ovary. Because these cysts are found near the ovary, they are casually referred to as *paraovarian cysts*. More precise identification can be achieved either through closer examination (the location relative to the ovary is very helpful), or by histopathology. Cysts of the epoophoron and paroophoron are movable cysts on the cranial surface of the ovary and have a thin wall of connective tissue and muscle fibers, are lined by low columnar epithelium with clear cytoplasm, and have a basement membrane. Follicles may protrude from the surface of the ovary, but are not movable.

Cystic rete (Fig. 4.28) develop from mesonephric tubules that form the rete ovarii within the ovary. Less commonly, cystic extraovarian rete are found. **Cystic rete tubules** have been observed in the bitch, queen, and cow. Those in the cow seldom attain significant size, but those of the bitch and queen become large enough to be confused with cystic follicles. Cystadenomatous tumors of the ovary may arise focally in these cysts.

Cysts of paramesonephric duct origin are very common in the mare. They are located on the fimbria of the oviduct and are called *fimbrial cysts, hydatids of Morgagni, or accessory oviducts.*

Cystic subsurface epithelial structures (cystic SES) of the bitch. The modified peritoneal cells covering the surface of the ovary of the bitch normally extend into the ovary a short distance where they are arranged as small single epithelial-lined cavities called "subsurface epithelial structures" or SES. Their importance is twofold. They frequently give rise to single, or more commonly, multiple cysts extending along the ovarian surface, and SES occasionally undergo neoplastic transformation. Neoplasms of the SES are usually adenomas, but carcinomas do occur. These tumors tend to form cysts and have a folded, papillary pattern.

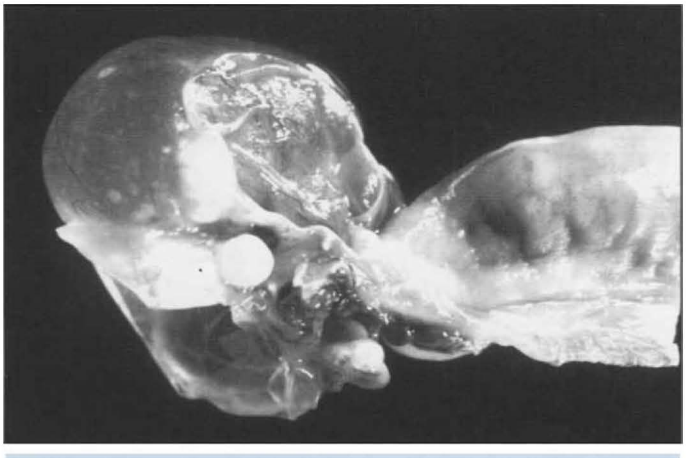

Figure 4.28 Cystic rete ovarii have replaced and compressed the remaining ovarian tissue in this cat. Cyst rete are common in queens and frequently occur in bitches. They develop in the hilar area of the ovary, a useful feature in identifying them both grossly and microscopically.

The incidence of cysts of the SES increases with age. They are small, seldom larger than 5 mm in diameter, and can be located anywhere within the ovary, but their relationship to the surface is usually obvious. These cysts are lined by cuboidal epithelium. They do not appear to have any effect on fertility but, since the SES are hormonally sensitive, cyst formation may be associated with hormonal dysfunction. The lining of the cysts, like the surface epithelium and the SES, expresses cytokeratin and this allows differentiation from atretic follicular cysts.

Germinal inclusion cysts of the mare

Entrapment of small segments of peritoneum is associated with ovulation, and in the mare leads to the development of inclusion cysts that are found near the ovulation fossa (Fig. 4.29). They are also referred to as *fossa cysts*. Although rather commonly encountered as one or a few small cysts lined by epithelial cells (small follicles are lined by granulosa cells) near the ovulation fossa, they are rarely numerous

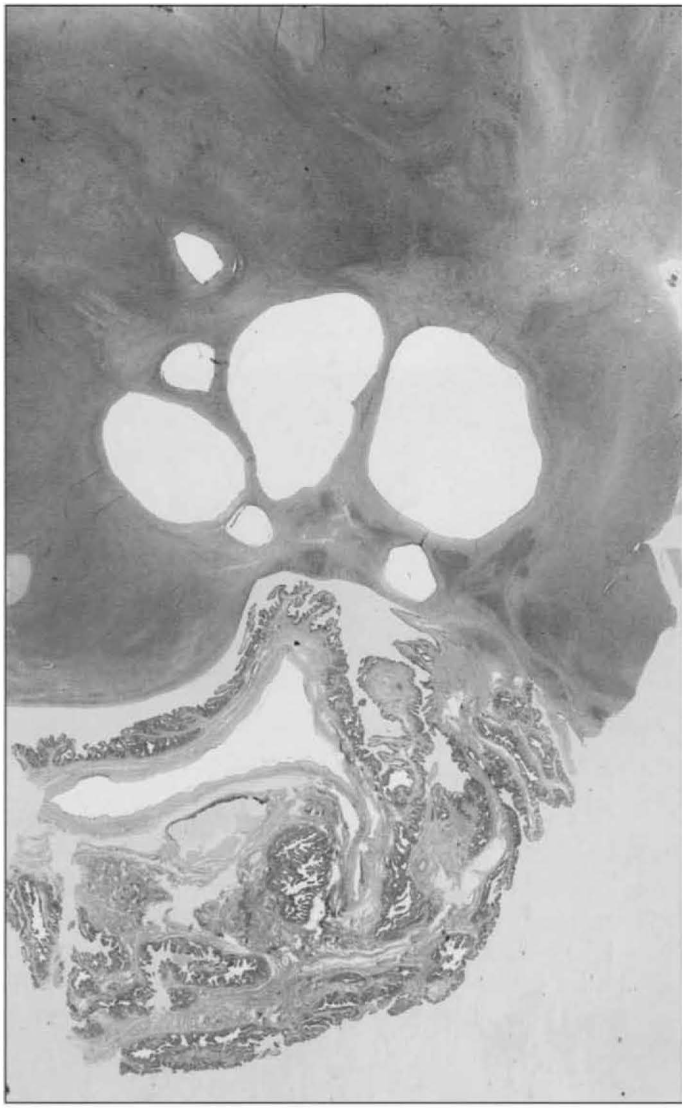

Figure 4.29 Germinal inclusion cysts adjacent to the ovulation fossa in a mare. The cysts form from small pieces of surface epithelium (modified peritoneum) that becomes entrapped after the surface is disrupted at ovulation.

or large enough to interfere with ovulation. Occasionally, their expansion can lead to atrophy of compressed ovarian tissue with loss of function (Fig. 4.30).

Cystic follicular disease

Anovulatory cystic ovarian disease occurs in most, if not all, species. Its importance as a disease entity varies greatly among species; in domestic species, *it is only a serious problem in cows and sows.* Cystic ovarian disease occurs infrequently in the bitch and queen and rarely in the ewe, doe, and mare.

Diagnosis depends in part on differentiating anovulatory cystic follicles from normal antral or tertiary follicles. An important criterion for this differentiation is size. Follicles larger than they should normally be at ovulation, persistence, and possible associated signs of hyperestrogenism are features of cystic follicular disease.

Tertiary follicles vary greatly in size between species, ranging from about 3 mm in the queen up to 7 cm in the mare! Normal follicular diameters near ovulation are approximately 2 cm in the cow, 1 cm in the sheep and pig, and 0.75 cm in the dog. Knowledge of the stage of the cycle is also helpful, but disappointingly is provided inconsistently in the histories provided with clinical case submissions.

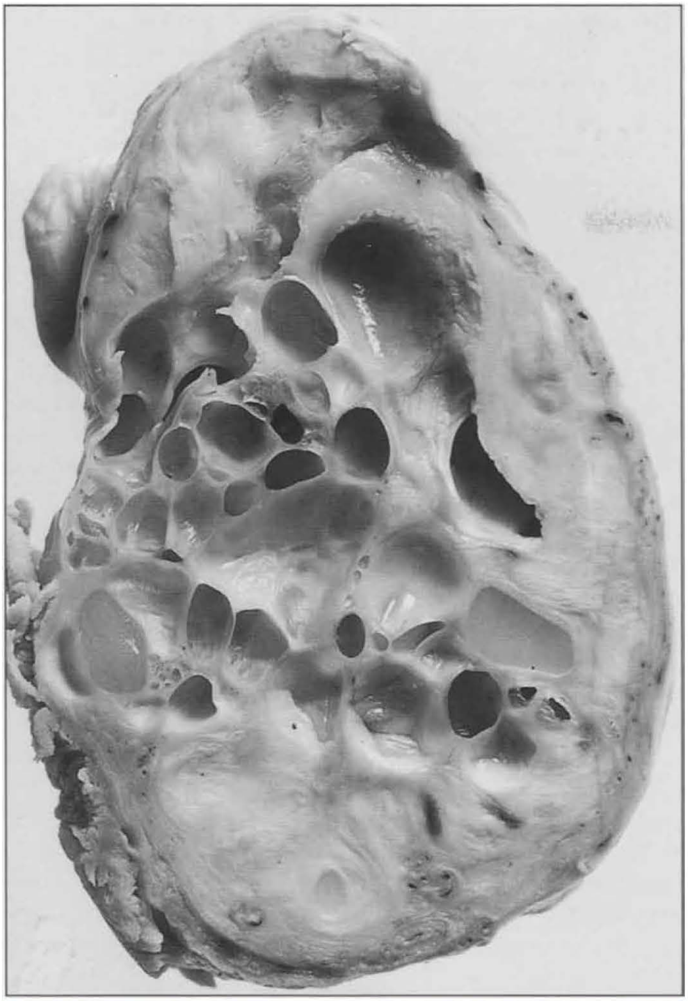

Figure 4.30 Multiple germinal inclusion cysts from a mare (hemisectioned ovary). (Courtesy of V Osburne.)

The examining pathologist should persist and insist on receiving as complete a reproductive history as possible.

It is only in cattle that the condition has received detailed study. Accordingly, the major consideration here is of the bovine disease.

Cystic ovarian disease in cows

A well-known feature of anovulatory follicular cysts is their relation to nymphomania, but *most ovarian cysts are not associated with signs of persistent estrus.* The behavior of cows with cystic ovaries is variable. The majority of cows with ovarian cysts are anestrous. The disease arises from the failure of mature follicles to ovulate. It occurs most often before the first postpartum ovulation. Approximately 45–60% of animals that develop anovulatory follicular cysts will re-establish normal ovarian cycles spontaneously. Cystic follicles may also develop after postpartum ovarian cycles have been established, and these cysts are more likely to persist if effective treatment is not instituted.

The *cause* of cystic ovarian disease is not understood in any species. The disease in cattle occurs more frequently after parturient or postparturient disease, and there is evidence that *intrauterine infections* play a role in the pathogenesis of the disease. There is clearly a *genetic predisposition* to the disease in certain families. The daughters of cows that have had cystic ovaries have a substantially increased risk of developing the disease as compared to the general population. The disease tends to involve primarily dairy cows, but it can occur in cattle of any breed if they are withheld from breeding for a prolonged period of time. One of the factors that has made the understanding of the disease difficult is the definition of the disease itself. *Follicular cysts in cattle are usually defined as follicles greater than 2.5 cm in diameter that fail to ovulate and may persist.* By the time a follicle can meet the criteria to be defined as cystic, the conditions that led to its formation have passed and are not available for study. To offset this difficulty, anovulatory ovarian disease has been produced by a variety of experimental techniques. Unfortunately it is not known whether any, or all, of the experimental manipulations induces anovulatory cystic disease by the mechanisms that operate in the natural disease.

The most widely held theory of the *origin of cystic ovarian disease* has involved aberration of the preovulatory surge of luteinizing hormone, either the absence of the surge or the mistiming of the surge. This hypothesis, or some modification of it, is still the most attractive. Cows that develop cystic ovaries as the result of estrogen and progesterone treatment have an increased mean basal concentration of luteinizing hormone secretion with increase in the frequency and amplitude of pulses, but the characteristic preovulatory luteinizing hormone surge is deficient. This increase in luteinizing hormone secretion is thought to be due to aberrant hypothalamic function altered experimentally by steroids or naturally by ovarian secretion.

The cysts may be single (Fig. 4.31) or multiple on one or both ovaries. These cysts may persist, but during the course of the disease additional cysts may be recruited and some cysts undergo atresia. Patches of luteal tissue can be seen grossly in the wall of some of the cysts and can be recognized histologically in about a quarter of them. The walls of the cysts show the same type of degeneration that occurs in normal atresia. Degeneration of the granulosa cells takes place first, the cells undergoing pyknosis and karyorrhexis and

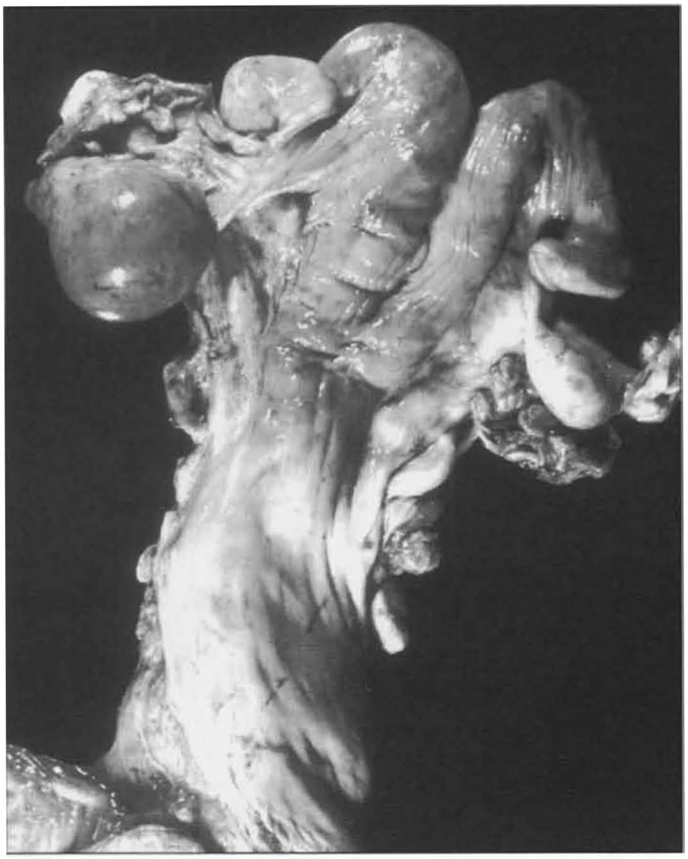

Figure 4.31 Cystic follicle in the ovary of a cow. This condition is thought to be due to inadequate luteinizing hormone release with persistence of the anovulatory follicle.

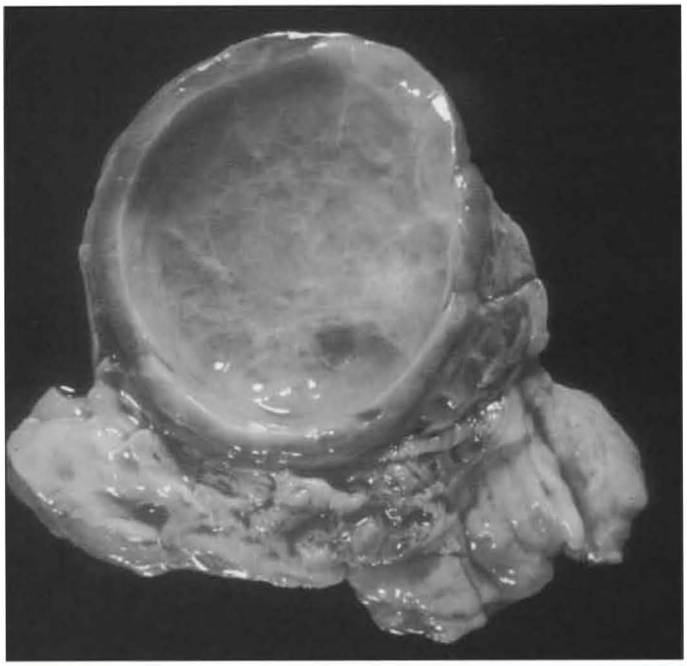

Figure 4.32 Luteinized follicular cyst from a cow. Note the uniform layer of luteinized granulosa cells, which both grossly and microscopically appear as luteal tissue, lining the inner wall of this anovulatory follicle. There is no ovulation papilla.

sloughing into the cyst lumen. The oocyte also undergoes degeneration. The changes of the theca interna are variable. The theca is partially luteinized in some cases, whereas in others it degenerates and is infiltrated by fibrous tissue. The luteal tissue may occur in patches or form a crescent of variable thickness.

Luteinized cyst

This type of cyst develops when ovulation fails to occur and the theca undergoes luteinization. There is no ovulation papilla and the luteal mass is smooth and rounded (Fig. 4.32). The cavity of the cyst is spherical and lined by a layer of fibrous tissue adjacent to the zone of luteinized cells. Luteinized cysts occur more frequently in *cattle and swine* than in other species of domestic animals. Partial luteinization of the wall of follicular cysts is a common feature in the bitch. In cattle, they usually occur as single cysts. Single luteinized cysts may occur in pregnant sows, but multiple cysts are associated with infertility.

Anovulatory luteinized cysts should not be confused with cystic corpora lutea. A cystic corpus luteum is a corpus luteum that has formed after ovulation and in which a central cavity has persisted in a mass of developing luteal tissue. Cystic corpora lutea are not evidence of ovarian malfunction. They form after ovulation, and they do not affect the length of the estrous cycle. If the cow has been successfully bred, the cavity will slowly become obliterated. Large central cysts may occasionally persist for 30–40 days after conception. *Cystic corpora lutea can be distinguished from luteinized cysts by the ovulation papilla that distorts the outline of the cyst at the point of ovulation.*

Ovarian epidermoid cysts have been recognized in cattle only recently. These are reported to be multiple and small and have a squamous epithelial lining that forms keratin.

Extraovarian lesions associated with cystic ovarian degeneration in cows

Changes in other organs develop only if the ovarian cysts persist. Since most cases are responsive to treatment, this is now the exception. It has been shown that in cystic ovarian disease the hormone limits are within normal levels; however, the toxicity of ovarian hormones depends not on the absolute levels, but in the loss of cyclicity and on persistence.

In established cases of cystic ovarian disease, *the uterus is usually altered*, the differences in degree being related to the duration of the condition. In association with functionally active follicular cysts, the uterus is enlarged and the wall is edematous (Fig. 4.33).

The *cervix* is enlarged, the external os patent, and the plicae edematous. The endometrium may appear grossly normal, being smooth, semitransparent, gray-pink, and moist. There may be some degree of *cystic endometrial hyperplasia* detectable by the naked eye as tiny gray-white elevated blisters in the surface of the endometrium, which is overlain by a thin layer of clear viscous mucus. The accumulation of mucus (*mucometra*) and the development of cystic endometrial hyperplasia progress with time and are most striking in those animals that have been affected long enough for atrophy of the ovarian cysts to have occurred and the animal to have become anestrous. By then, the endometrium has become very cystic and the volume of mucus accumulated to 100–1000 mL or more.

The cervix may be hypertrophic or atrophic, as described above. It usually contains thick, viscid, gray-white, and cellular mucus.

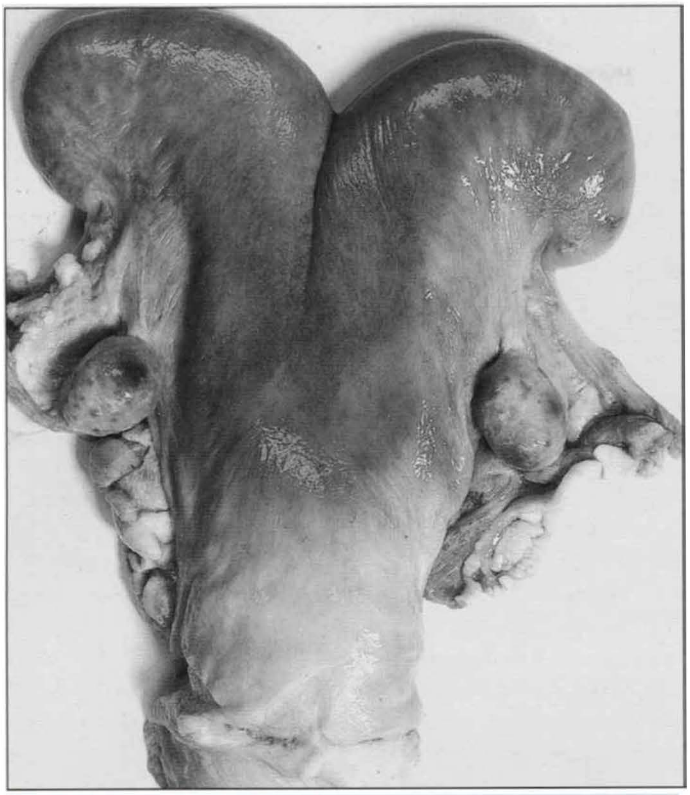

Figure 4.33 Mucometra in the uterus of a cow with a follicular cyst. The endometrium undergoes hyperplasia caused by the long-term release of estrogens from follicular cysts.

The epithelium undergoes squamous nonkeratinizing metaplasia of mild degree. The vagina is edematous when the cysts are active, but otherwise the most striking change is the formation of *cysts in Gartner's ducts*. These mesonephric duct vestiges that lie in the wall of the vagina, one on each side of its floor, are normally visible only microscopically as continuous or discontinuous ducts lined by a simple pavement or cuboidal epithelium. When chronically stimulated by estrogen, the epithelium becomes squamous and the ducts cystic and visible, or palpable, as a series of blebs or as tubules up to 1.0 cm in diameter on the floor of the vagina.

Cystic Gartner's ducts are usually accompanied by *cystic Bartholin's glands*. Either may become abscessed. Bartholin's glands, one on each side of the floor of the vulva, undergo cyclic secretory changes during the estrous cycle and a squamous epithelium on the ducts is normal in estrus. Exaggeration of this change following long-term exposure to estrogens causes occlusion of the ducts and the formation of retention cysts. The vulva may be edematous when the cysts are active, and the clitoris may be enlarged in long-standing cases.

Cystic ovarian degeneration in other species

In **swine**, *cystic ovaries are common and are important as a cause of infertility*. Failure of a single follicle to ovulate need not interfere with pregnancy and single large cysts, 2–3 cm in diameter, may be found in pregnant animals. They are presumed to represent mature follicles that did not ovulate, but single anovulatory cysts may also be associated with irregularity of the estrous cycle. The association is more clearly manifested with multiple cysts. The cysts vary in type from follicular, which are lined by normal granulosa cells, to luteinized cysts. Multiple luteinized cysts with some cysts up to 5 cm in diameter are a distinctive feature of cystic ovarian disease in swine. The luteal tissue may form a complete rim or be present in patches. The endometrium in cases of multiple luteal cysts shows hyperplasia of progestational type, and in long-standing cases the clitoris is enlarged.

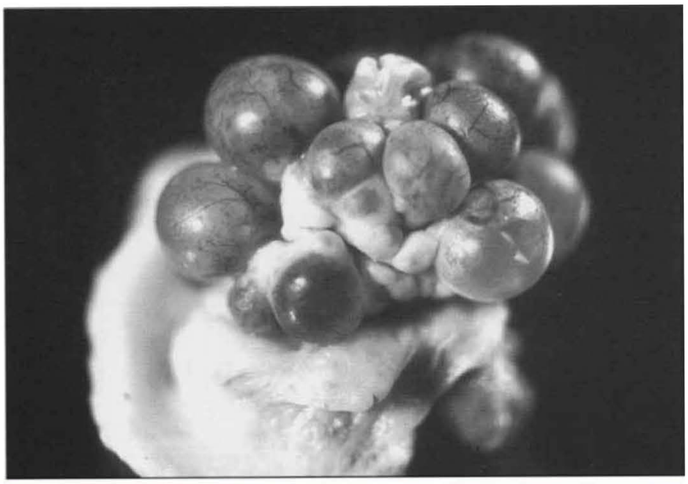

Figure 4.34 Multiple follicular cysts in a bitch. Many of the nodular structures have the appearance of corpora lutea. Some appear as more typical follicles containing clear fluid, though larger than normal. These are cystic follicles in which the inner walls of the anovulatory follicles have undergone partial luteinization.

Cystic degeneration of the Graafian follicle with the associated loss of cyclicity and infertility comparable to that of the cow and the sow does not appear to occur in the **mare**, but the matter is not clear because anovulatory follicular cysts do develop during the winter anestrous period, and some of these mares will show irregular signs of estrus. The number and size of these anovulatory cysts vary considerably. There is no evidence that development of these cysts, regardless of their size, is indicative of reproductive disease.

In the **bitch**, anovulatory cysts of both follicular and luteinized type tend to occur in older age groups. Grossly they tend to be multiple and commonly have partial luteinization of cyst walls (Fig. 4.34). The incidence of cystic ovarian disease is low in the bitch, but there is some confusion on this point because cystic rete tubules, cysts of SES, paraovarian cysts, and cystadenomas have been confused with follicular cysts.

Polycystic ovarian disease in the bitch is rare, but, because it can cause hyperestrogenism, it carries a special risk in the dog because of the species' sensitivity to either endogenous or exogenous estrogen, which can induce lethal bone marrow suppression. The condition can involve either one or both ovaries, the affected ovary being greatly enlarged by multiple, thin-walled cysts that vary from 1 to 12 mm in diameter. The disease develops in mature animals that may be either nulliparous or multiparous. If clinical signs occur, they are apt to be associated with *hyperestrogenism* and include persistent estrus with cornification of the vagina and swelling of the mammary glands or the toxic effects of hyperestrogenism on the bone marrow with resultant pancytopenia. This pancytopenia can result in anemia, thrombocytopenia with bleeding, most often occurring as epistaxis, or granulocytopenia with increased susceptibility to infection. The mechanism of the inhibitory action of estrogen on the hematopoietic tissues in estrogen-sensitive species is not known. Estrogen appears to inhibit the differentiation of pluripotent stem cells while stimulating the differentiation and maturation of committed stem cells.

Most of the cysts are obviously of follicular origin but in various stages of atresia. Degenerating oocytes can be identified in some of the cysts, but the disease is not just one of anovulation because in some cases hundreds of follicles have been recruited. The granulosa and theca lining of the cysts is attenuated in the larger ones. Patchy areas of luteinization form in the walls of some of the cysts. This luteinization may involve individual cells or sheets of cells and either the theca or the granulosa.

NEOPLASTIC DISEASES OF THE OVARY

General considerations

Enlargement of the ovary or localized tissue proliferation within the ovary can result from a number of conditions that include: normal cyclical changes (tertiary follicles, developing corpora lutea), atretic follicles (autumn follicles in the mare), hematoma, oophoritis, or cysts of ovarian or paraovarian structures. These conditions must be differentiated from primary ovarian neoplasms that occur with variable frequency in all species of domestic animals.

Ovarian neoplasms tend to occur in mature or older animals and may be associated with behavioral changes or changes in target tissues if the tumor is functional (e.g., stallion-like behavior in mares with granulosa cell tumors that are producing androgens). Although rare, metastases from neoplasms in other sites may also be found in ovaries.

Tumors arising from tissues that are specifically ovarian can be divided into three broad categories: tumors of the **surface celomic epithelium**, tumors of the **gonadal stroma**, and tumors of **germ cells**. Tumors developing from nongonadal supporting tissues of the ovary can be of the usual variety of fibroblastic, smooth-muscle, and vascular tumors, but are, in fact, uncommon in domestic animals.

Tumors of the surface epithelium and its tubular invaginations, the SES, give rise to *papillary and cystic adenomas* and, less frequently, *papillary adenocarcinomas*. These tumors are common only in the bitch among domestic animals.

Gonadal stromal tumors are tumors of granulosa and theca cells and their luteinized counterparts. They are also referred to as *sex cord-stromal tumors* to reflect the concern that the granulosa cells may arise from the sex cords of the surface celomic epithelium or the mesonephric tubules. In spite of the histogenetic uncertainty, these tumors must be dealt with as a group because *granulosa cells and theca cells often coexist in the same tumor*. This tendency to coexistence is dealt with by hyphenation, referring to the tumors as *granulosa-theca cell tumors*. Included in this group are tumors that resemble testicular tumors of the Sertoli cell and Leydig cell types. Whether these are, in fact, Sertoli cells and Leydig cells or whether the ovarian stromal cells are merely growing in patterns of their testicular homologs is difficult to determine. The question is made more difficult by the fact that *this group of tumors frequently produces hormones*. The hormones are sometimes appropriate products for the apparent cells of origin, that is, estrogens and progesterone, but many of the ovarian stromal tumors produce androgens. This is particularly true of the ovarian tumors of the mare. It is not useful to attempt to classify ovarian tumors on the basis of hormone production, because, in addition to variations in hormone production from a single class of ovarian tumors, variation in hormone production from a single tumor can occur over time.

The **germ cell tumors** of the ovary, like their testicular counterparts, arise from germ cells, and are usually divided into two main categories in domestic animals: the **dysgerminoma** and the **teratoma**. *The dysgerminoma is composed of cells that show morphologic similarity to primordial germ cells and resemble their testicular homolog, the seminoma. In teratomas, totipotential germ cells have undergone somatic differentiation giving rise to two or more germinal layers with a variety of tissues present in the tumors.* Germ cell tumors are rare in domestic species, except for the testicular seminoma of dogs, and further subdivision of these two categories is probably unwise at this time; however, some germ cell tumors do not fit well into this simple two-category classification. When more extensive series are available for study and analyzed by sophisticated methods, it is likely that the germ cell tumors of animals will show the wide variability that human germ cell tumors display. In addition to the germ cell tumors that show no somatic differentiation (the dysgerminomas and the seminomas) and tumors that have extensive differentiation into tissues of multiple germinal layers (the teratomas), human germ cell tumors have shown various stages of differentiation, i.e., endodermal sinus tumors (yolk sac tumors), choriocarcinomas, and embryonal carcinomas, as well as tumors from single germ layers. This is the variability that is to be expected in tumors arising from pluripotential germ cells.

Ovarian tumors occur most frequently in the bitch, mare, and cow. In the bitch, they are often bilateral, especially those arising from the surface epithelium and the SES. In the cow, ewe, and mare, they are usually unilateral and of the gonadal-stromal type. In cows, there is a tendency for the tumor to occur in the daughters of affected dams and, in these animals, removal of the affected ovary may be followed by the development of a tumor in the other ovary. Very few ovarian neoplasms have been reported in the feline and porcine species. The tumors of the cat are similar to those of the bitch.

Sex cord-stromal tumors

These tumors arise from sex cords or the ovarian stroma and include granulosa cell tumors and tumors of the theca or, rarely, luteal tissue.

The **granulosa-theca cell tumor** is the most common tumor in this group. They are *generally unilateral, usually nonmalignant tumors* in any species. Although they may be observed in young animals, the incidence increases with age. Part of their interest lies in the production of steroids by these tumors.

In *mares*, in which species the tumors are common and have been studied most carefully, three behavioral patterns have been recognized: *anestrous, continuous or intermittent estrus, and male behavior*. Surprisingly, testosterone levels in the peripheral plasma are elevated in most cases. Male behavior is usually only seen in those cases in which the testosterone levels are above 100 pg/mL plasma. Some mares with granulosa-theca cell tumors also have elevated estrogen levels, but these elevations are less clearly related to behavioral patterns. Even in cases in which hormone production associated with the tumor is low, *atrophy of the opposite ovary usually occurs*. The cause of this atrophy has not been determined. It was thought to be the result of testosterone production by the tumor, but convincing association between testosterone levels and ovarian atrophy has not been established, and androgen production by tumors other than the granulosa-theca group has not caused atrophy of the contralateral ovary. Granulosa cells produce the peptide hormone, *inhibin*, which inhibits release of follicle-stimulating hormone. This hormone has been demonstrated to be elevated in granulosa cell tumors, and it may be that the production of inhibin produces the characteristic ovarian atrophy seen in this disease. Normal function of the atrophic ovary usually returns within a year of removal of the tumor. In bitches with sex cord-stromal tumors, *cystic endometrial hyperplasia and pyometra* are common. Vaginal changes can be used to monitor estrogenic influences.

The surface of the granulosa-theca cell tumor is smooth (Fig. 4.35) and the cut surface may be solid or cystic (Figs 4.35, 4.36). The solid portions of the tumor are white or yellow, depending on the lipid content. The cells in these tumors resemble their counterparts in normal follicles, but their histologic arrangement is quite varied. These tumors commonly contain areas with characteristic gland-like or rosette patterns of abortive follicles, some of which may contain a secretory globule resembling an ovum and called a *Call–Exner body* (Fig. 4.37A).

This type of differentiation is frequently observed in the early stages of development of bovine neoplasms, but is less common in other species and in large tumors. Instead, the arrangement of cells is usually diffuse with, in some tumors or parts of tumors, pseudoalveolar pattern, depending on the disposition of the stroma. There is a tendency for some granulosa-theca cell tumors to develop a tubular pattern similar to that of the Sertoli-cell tumor of the testis (Fig. 4.37B). The stroma consists of broad irregular bands of dense collagen. Cyst formation and hemorrhage are common. The more thecomatous portions of such tumors may resemble normal theca cells and, at the other extreme, be distinguishable from plump fibroblasts only by the demonstration of sudanophilic droplets in the cytoplasm or by histochemical techniques for steroids.

The cysts that often make up the bulk of the tumor are lined by granulosa cells that are surrounded by a variable population of thecal cells (Fig. 4.38). In some equine tumors, particularly those associated with high testosterone levels, embedded in the thecal cell layer are large polyhedral eosinophilic cells resembling the testosterone-producing Leydig cells. Ancillary diagnostic testing includes endocrinology. Testosterone and estradiol concentrations tend to be variable, but α-inhibin concentrations have been shown to correlate to tumor mass and to be more consistently elevated.

Tumors composed only of theca cells, **thecoma** or **luteoma**, are much less common in all domestic animals than those arising from granulosa cells or containing a mixture of theca and granulosa cells. The few tumors reported have been firm, white-to-orange, and composed of streaming oval or spindle cells that resembled the cells of the theca interna. The demonstration of lipid in the cytoplasm allows differentiation from fibromas.

Tumors of the surface celomic epithelium

Neoplasms arising from the epithelium covering the surface of the ovary are very important tumors in women, but in nonhuman mammals, they occur commonly only in the bitch. *Papillary cystadenoma and cystadenocarcinoma* have been reported primarily in the bitch. As with the granulosa theca-cell tumor, many of the affected bitches have *cystic hyperplasia of the endometrium*. It should be emphasized that hyperplasia of the endometrium has been observed in bitches with a variety of ovarian neoplasms. It appears that the tumor, irrespective of type, may occasionally stimulate the ovarian stroma with concomitant production of steroid hormones. Papillary cystadenocarcinomas should be considered in the differential diagnosis of *ascites* in adult entire bitches. The ascites develops from obstruction of the diaphragmatic lymphatics by permeating tumor fragments, with perhaps a contribution by secretion by the tumor epithelium. The tumors are frequently multicentric in origin and bilateral. They vary in size from small neoplasms that are not detectable on gross examination to irregular-shaped masses 10 cm or more in diameter. Confinement of the tumor within the rather complete ovarian bursa of the bitch, with consequent compression of the papillae, gives them a typical cauliflower-like appearance (Fig. 4.39A). Once free of the bursa, the papillary nature becomes obvious (Fig. 4.39B) and peritoneal implantation occurs readily. The presence of such papillae is indicative of malignancy. Cysts of various sizes are usually scattered throughout the neoplastic mass (Fig. 4.40).

The epithelium varies from low cuboidal to columnar, with stratification in some areas, and mitotic figures are scant, even in the malignant form. The tumor appears to develop from the surface and from tubular structures (cortical tubes, SES) of the ovarian cortex. Many of the tubules are continuous with the surface epithelium and responsive to estrogenic stimulation. Papillary tumors have been induced in the bitch by prolonged administration of diethylstilbestrol. The experimentally induced tumors regress following withdrawal of hormone treatment. *Tumors of the surface epithelium can occur in association with sex cord-stromal tumors*, possibly by hormonal induction by the granulosa-theca tumors. *The separate identification of the two tumors can be difficult, particularly in areas where the tumors join, but is aided by immunohistochemical staining.* Cytokeratin intermediate filaments are expressed in the surface epithelium and the SES. On the basis of limited investigation, it appears that this specificity has been conserved during tumor development, and affords easy differentiation of the above from cytokeratin-negative tumors of the sex cord-stromal group.

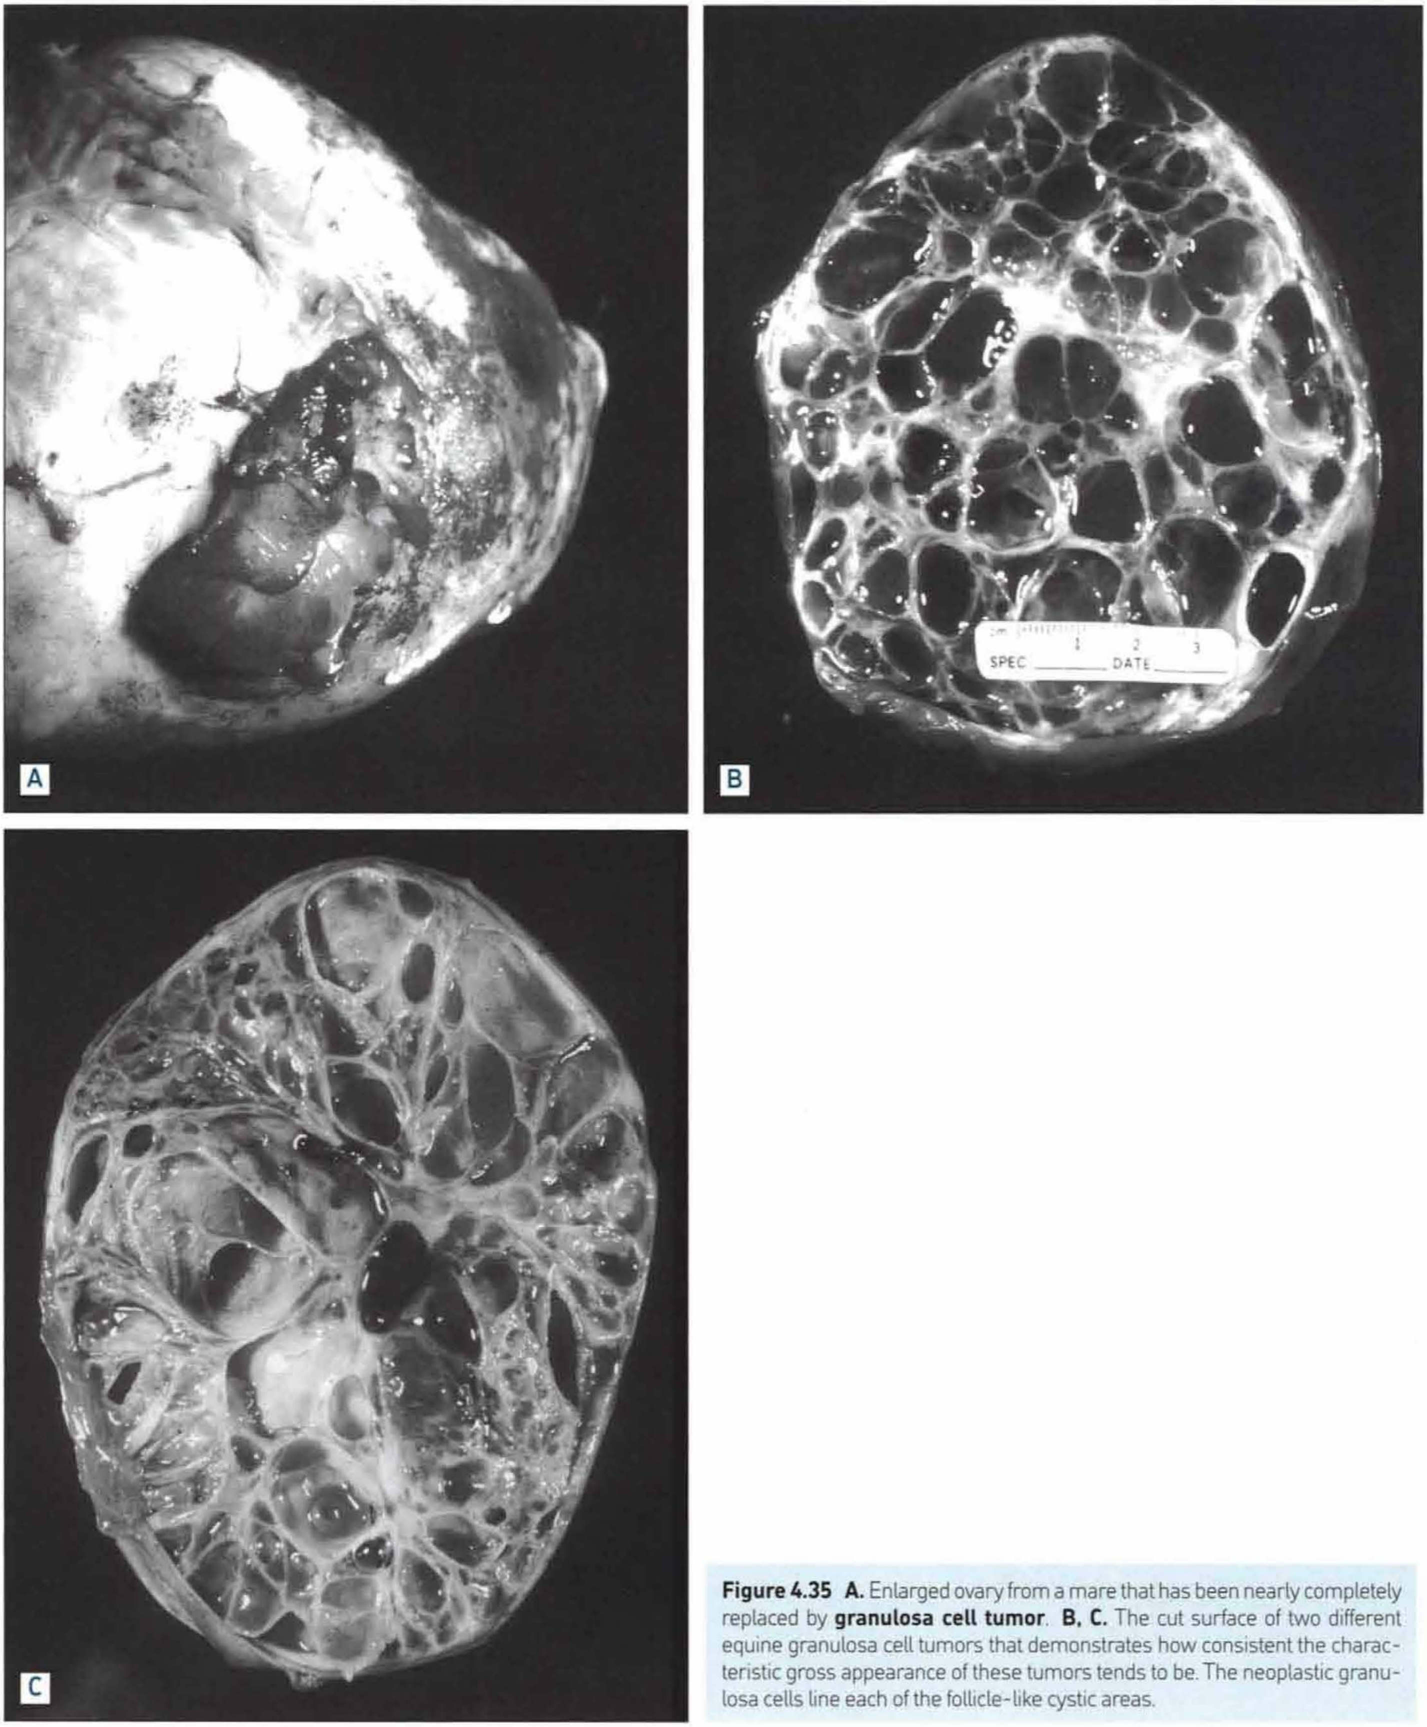

Figure 4.35 **A.** Enlarged ovary from a mare that has been nearly completely replaced by **granulosa cell tumor**. **B, C.** The cut surface of two different equine granulosa cell tumors that demonstrates how consistent the characteristic gross appearance of these tumors tends to be. The neoplastic granulosa cells line each of the follicle-like cystic areas.

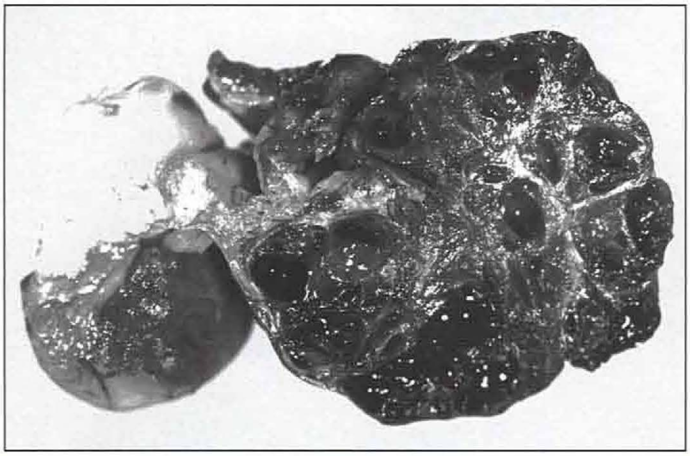

Figure 4.36 **Granulosa cell tumor** extending from the surface of the ovary from a bitch. Note the similar cystic pattern as that seen in the equine granulosa cell tumors in Figure 4.35. Following surgical removal, the fluid within the cystic spaces is commonly hemorrhagic.

Tumors of germ cells

The **dysgerminoma** is a *rare tumor* that is comparable to the more common seminoma of the testicle in gross and microscopic features. *It is usually unilateral and has been observed in the bitch, cow, mare, and sow.* The tumor is smooth, or nearly so, and relatively soft. The cut surface is gray and may have areas of hemorrhage or yellow patches of necrosis. It is composed of a uniform population of large rounded cells with large central chromatic nuclei. Mitotic figures and giant cells are frequent. The pattern of growth is diffuse; the stroma is always scanty. Just as in the canine testicular seminoma, accumulations of lymphocytes are present within the tumors.

As the tumors are uncommon, it is difficult to generalize as to age of occurrence and clinical behavior in various species. In the bitch, in which most cases have been reported, the tumor is one of advanced age, and metastases have occurred in 10–20% of the cases. They have a more aggressive biological behavior in horses.

Ovarian teratomas *are rarely observed in domestic animals, but have been reported in the bitch, sow, mare, and cow.* Most are well differentiated and benign. They usually have solid and cystic areas containing

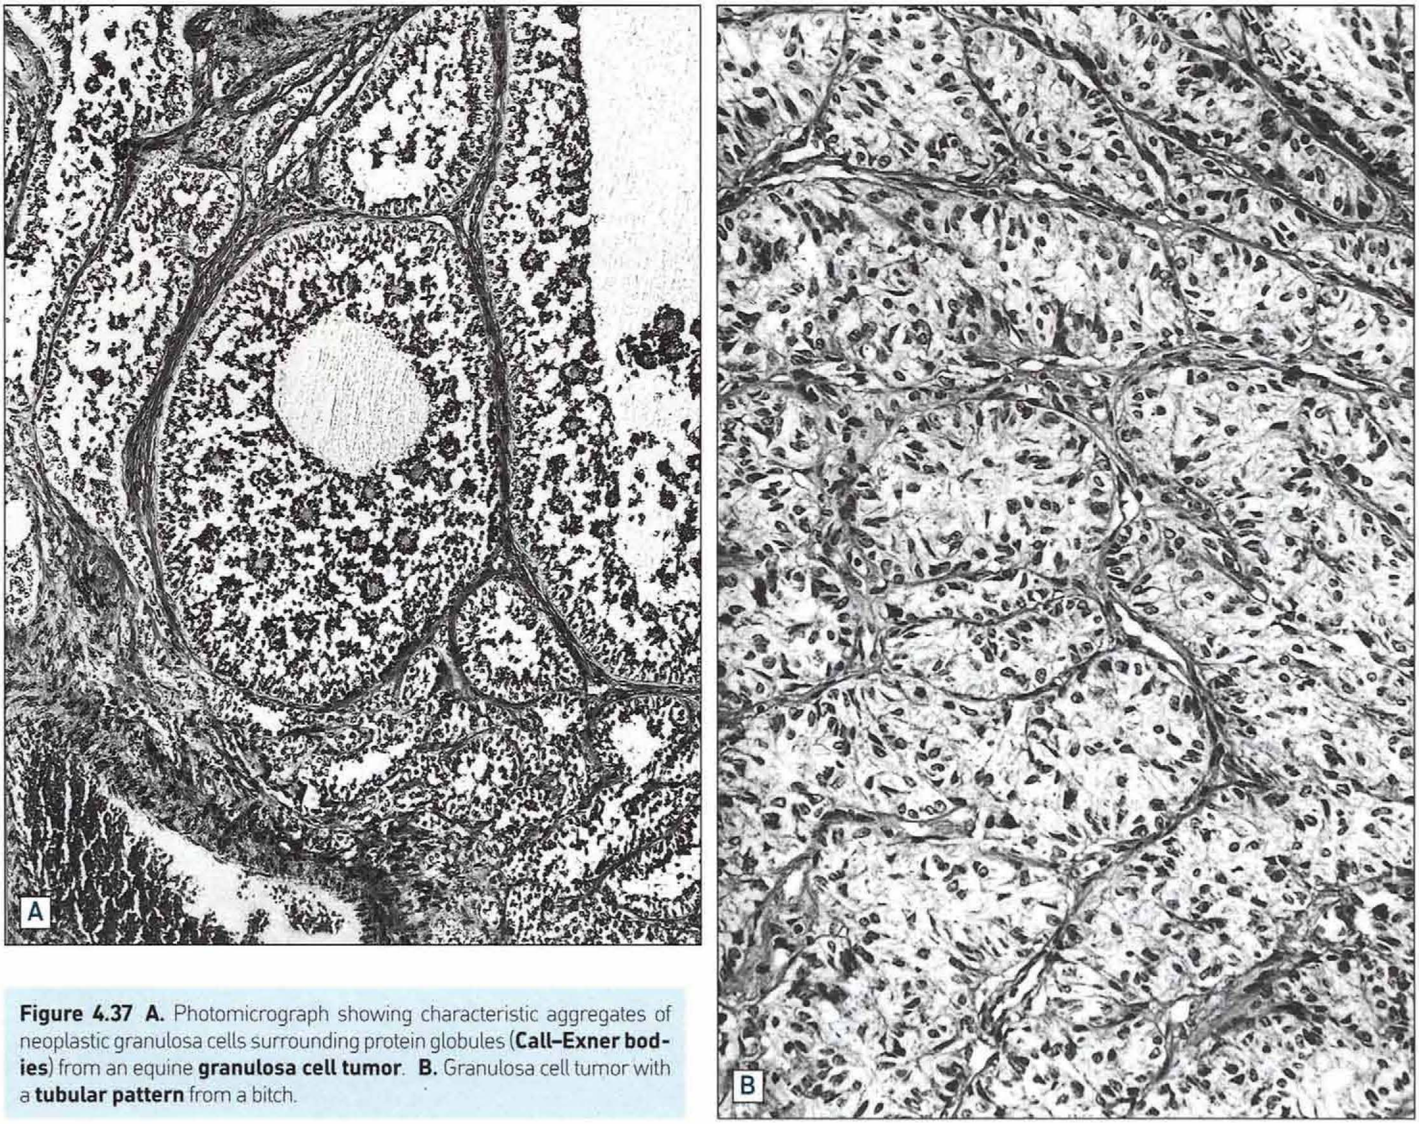

Figure 4.37 A. Photomicrograph showing characteristic aggregates of neoplastic granulosa cells surrounding protein globules (**Call-Exner bodies**) from an equine **granulosa cell tumor**. **B.** Granulosa cell tumor with a **tubular pattern** from a bitch.

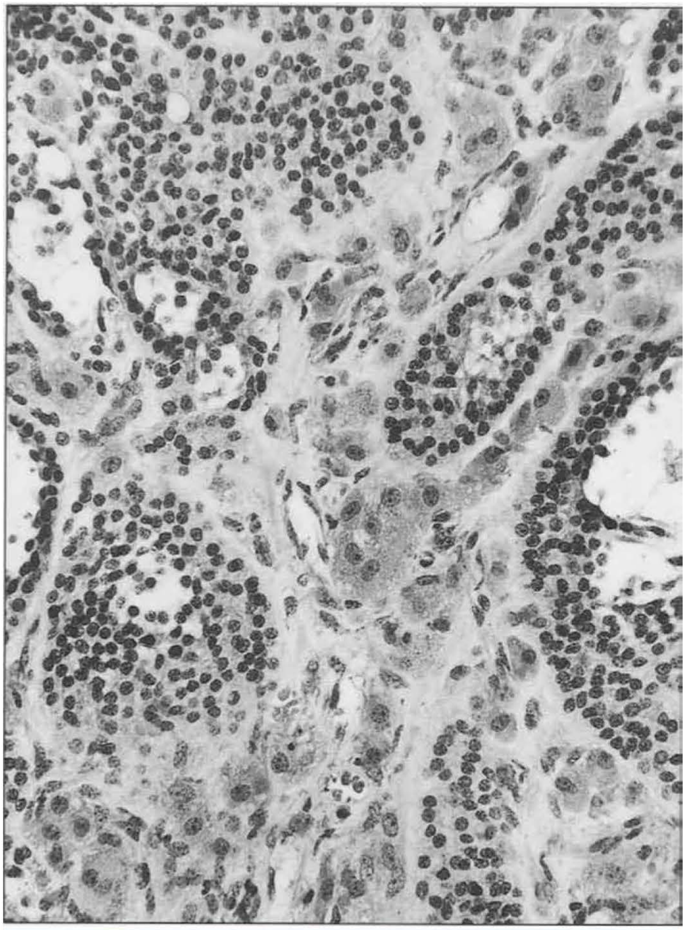

Figure 4.38 Photomicrograph of a **granulosa-thecal cell tumor** from a mare demonstrating presence of both neoplastic granulosa cells and the presence of many interstitial cells.

sebaceous material and hair (Fig. 4.41). A wide variety of other tissues is often present, including neural tissue, adipose tissue, bone, teeth, and respiratory epithelium (Fig. 4.42).

There were several theories on the histogenesis of teratomas, but it is now believed that the benign cystic ovarian teratomas are *parthenogenic tumors* that develop from a single germ cell that has completed its first meiotic division, but not its second. The evidence for this has come from a series of elegant cytogenetic and biochemical studies that have shown that tissues from ovarian teratomas are unique in that they are XX diploid cells, but are homozygous at chromosomal loci for which the host is heterozygous. This lack of heterozygosity is most reasonably explained as being the result of meiotic division.

Tumors of nongonadal tissues

Ovarian hemangioma is rare in all domestic animals except the pig, in which species it is the most common ovarian tumor in mature and aged sows. Ovarian hemangiomas are globular, well circumscribed, and tan to red-brown. Their surface is smooth and glistening and contains prominent vessels. The tumors arise in the ovarian cortex, and they are occasionally bilateral. The tumor is composed of well-differentiated endothelial cells that line vascular clefts and spaces. The tumors are often subdivided by bands of connective tissue. Malignant vascular tumors of the ovary have not been reported.

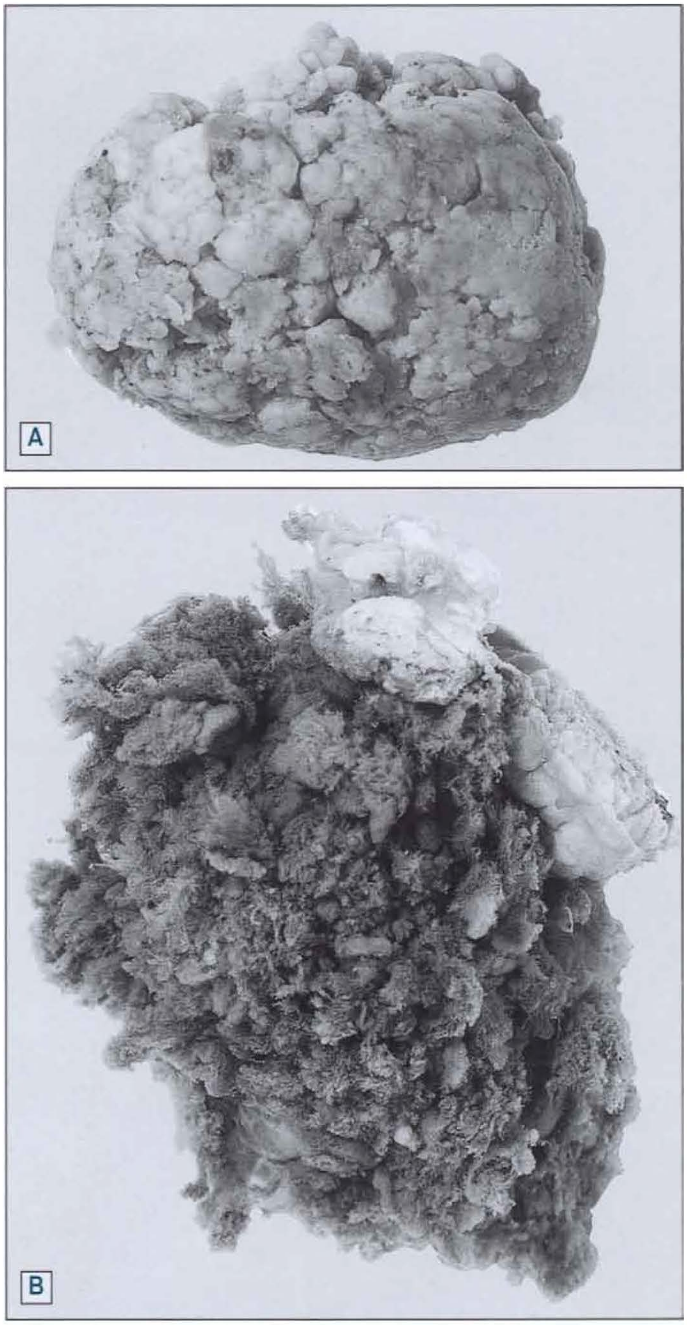

Figure 4.39 Papillary cystadenocarcinoma of the ovary, bitch. **A.** The ovary is contained within the bursa and its surface is irregular and cauliflower-like. **B.** When growing free of the bursa, the villous nature of the tumor is more apparent.

Ovarian tumors of other supporting tissues are very infrequent. **Leiomyomas** developing from the smooth muscle in the mesovarium have been reported in the bitch, queen, and sow, and mesovarial leiomyomas have been induced in rats treated with β-adrenergic receptor stimulants.

Lymphoma can affect the ovary of cattle. Neoplastic foci tend to develop within corpora lutea (Fig. 4.43).

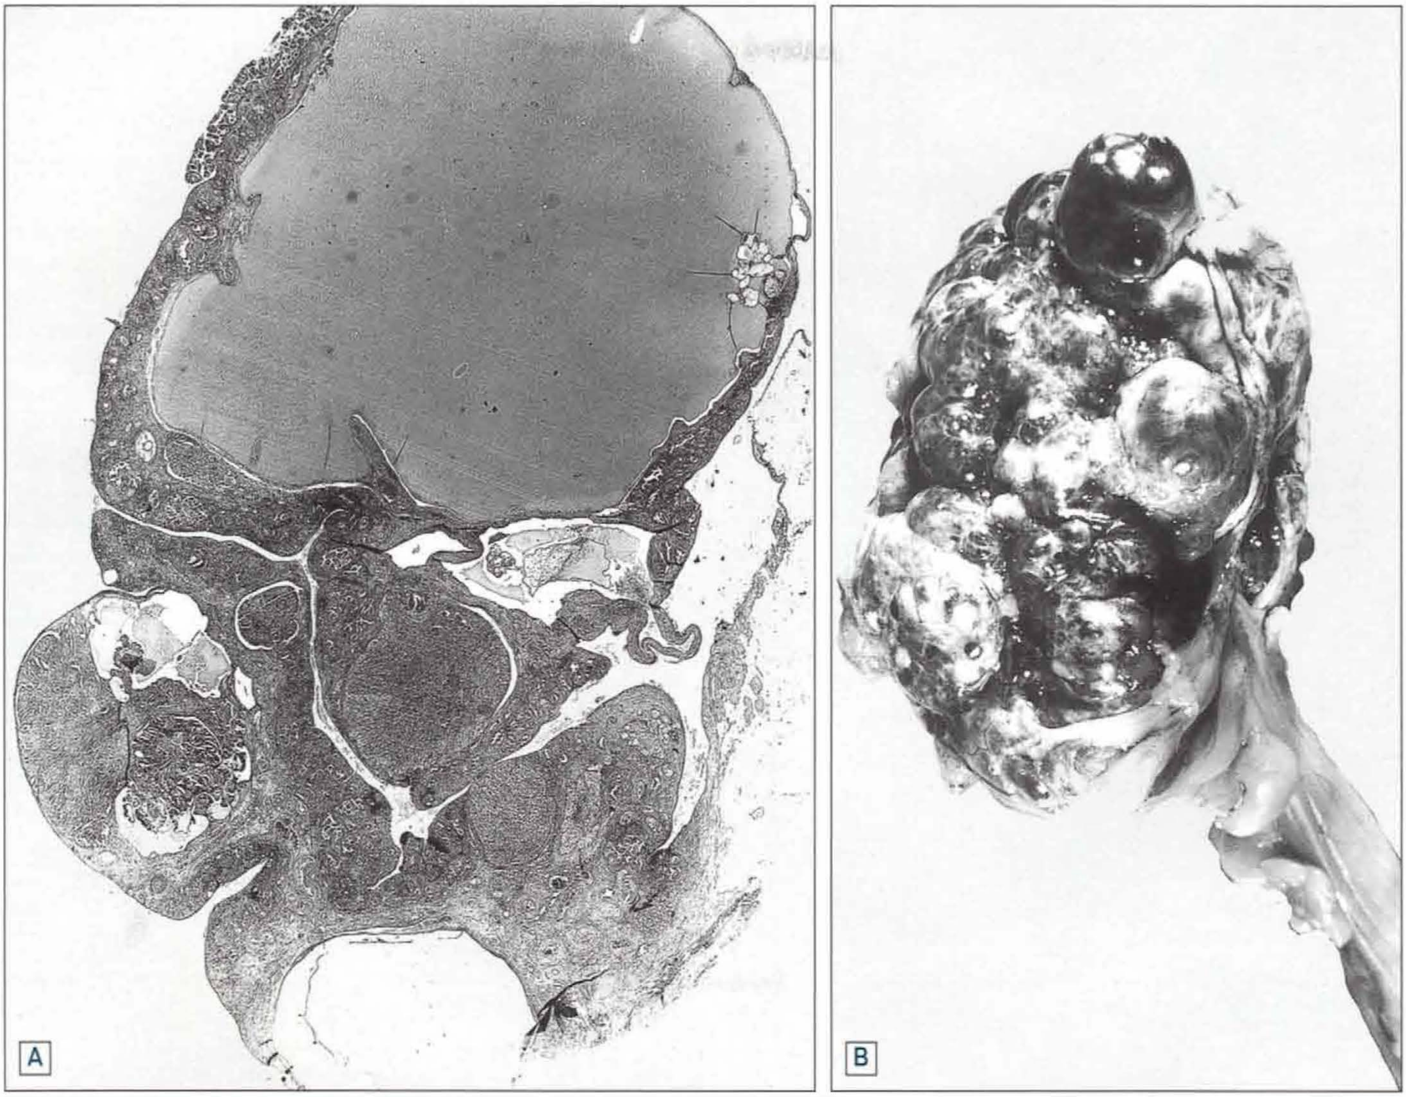

Figure 4.40 A. The cut surface of canine ovary with **papillary cystadenocarcinoma**. This neoplasm develops from the subsurface epithelial structures and is a common ovarian tumor in older animals. The neoplasm usually has a pattern of cystic structures with prominent papillary ingrowth into their cavities. **B.** The bursa has been removed, revealing the very irregular neoplastic growth pattern.

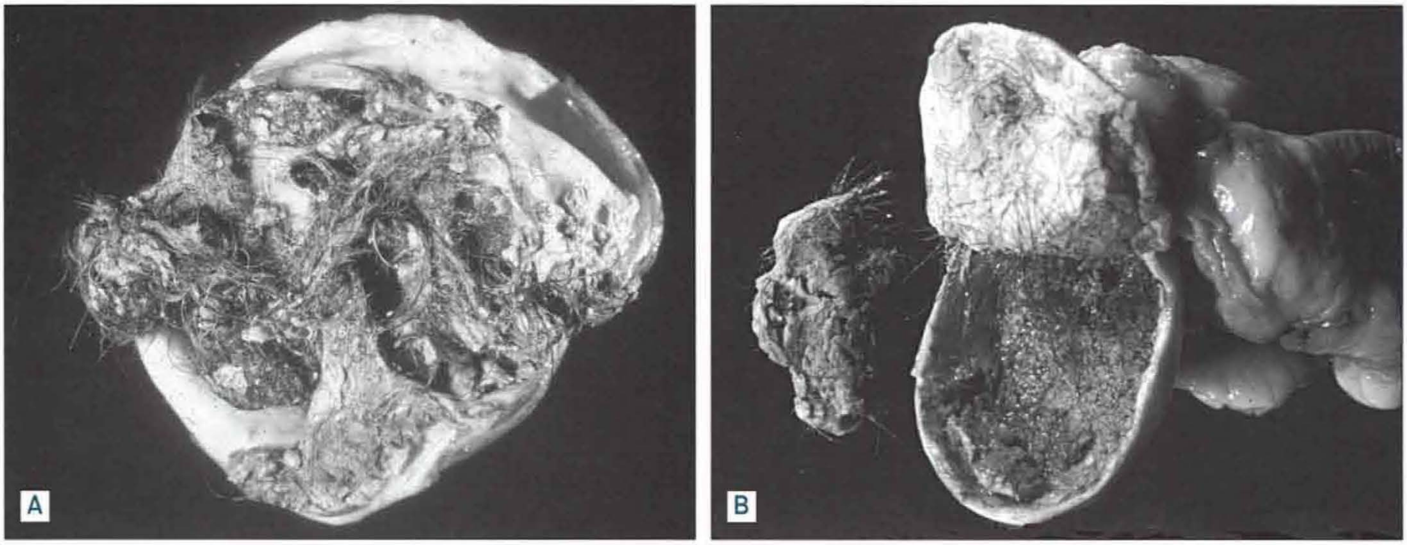

Figure 4.41 A. Equine ovarian teratoma. The normal ovarian parenchyma has been completely effaced by a large cystic mass containing mats of hair. A variety of tissues can often be identified in these tumors, including bone, teeth, and muscle. **B.** Opened **granulosa cell tumor** from a **bitch**. The wall contained firm areas and the central cavity was lined by dermis with hair.

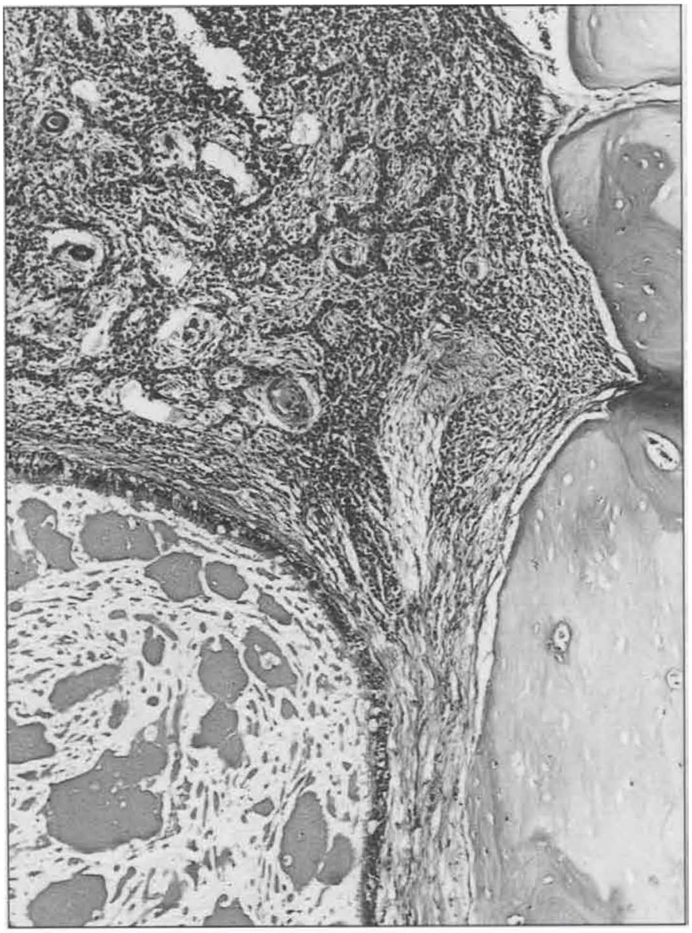

Figure 4.42 Photomicrograph of a **typical teratoma** showing the presence of multiple tissue types.

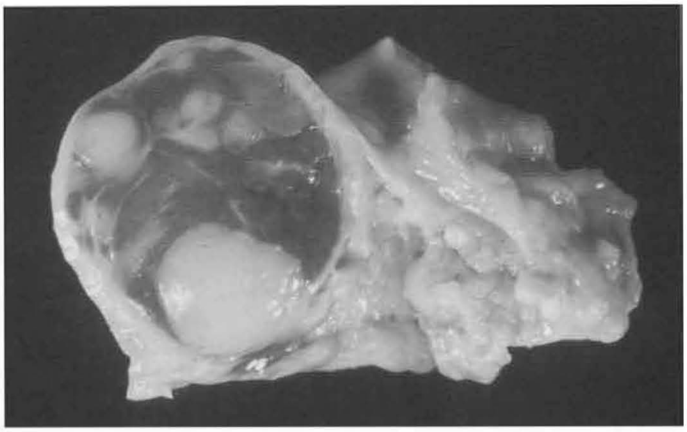

Figure 4.43 Bovine ovarian lymphosarcoma. Several soft pale masses of neoplastic lymphocytes are present within a corpus luteum. Although the uterus is commonly involved, corpora lutea seem to be the tissue within ovaries that are most commonly involved.

Metastatic tumors

Secondary tumors of the ovary are probably not less rare than primary ones, the relatively high incidence largely being attributable to secondary deposits of lymphomas. Mammary carcinomas in the bitch and intestinal carcinomas in the cow may metastasize to the ovary and apparently have an affinity for corpora lutea.

Vascular hamartomas

Vascular hamartomas of the ovary are included with tumors because they may be confused with neoplasms, and because granulosa theca-cell tumors occasionally occur in the same gonad. *Hamartomas are tumor-like malformations that are present at birth* and cease to grow after the animal reaches maturity unless the mass is subjected to trauma, infection, or vascular embarrassment. They have been observed in the cow and sow. The mass of malformed vessels may vary in size from those barely visible on gross examination to those weighing several kilograms. The smaller hamartomas are composed principally of mature-appearing, tortuous arteries and veins with relatively little intervascular connective tissue. In the mature individual, the increase in size of the hamartoma is due to thrombosis, with subsequent edema, hemorrhage, and necrosis, followed by proliferation of fibrous connective tissue. Small hamartomas are clearly demarcated from the adjacent ovarian tissue, but the ovary is gradually replaced as the mass enlarges. *The distinction between hemangiomas and vascular hamartomas is a difficult one*, and it may be that some of the reported ovarian hemangiomas are in fact vascular hamartomas that have grown as the result of vascular accidents.

PATHOLOGY OF THE UTERINE (FALLOPIAN) TUBES

Primary lesions in the uterine tubes are uncommon. *Hydrosalpinx, pyosalpinx, and salpingitis* are the only ones of importance, and these are usually secondary to disease of the uterus or to manual manipulation of the ovary. As regards incidence of salpingeal lesions, the only agreement is that they are much more common than is their diagnosis. They are recognized to be important in the cow and sow, but not in other species.

Hydrosalpinx

Hydrosalpinx is so called because the uterine tube is distended, uniformly or irregularly, up to 1.5 cm or so with clear watery mucus that fluctuates. The tube is also increased in length and tortuosity and is thin-walled. Histologically, there may be extensive multilocular cyst formation in the mucosa with obliteration of the lumen, and, in some chronically inflamed uterine tubes, there is extensive interstitial fibrosis.

Distension of the uterine tube by fluid follows loss of patency of the lumen (Fig. 4.44). *The obstruction may have a congenital or inflammatory basis.* Congenital anomalies involving the tubes are very rare, except in freemartins, but secondary hydrosalpinx can be associated with obstructions and segmental aplasias of the uterine horns. In the latter instances, the apex of the horn is usually distended with fluid also. Acute septic inflammations are more likely to produce *pyosalpinx*; chronic infective inflammations tend to produce loculations and stenosis of the lumen with *secondary hydrosalpinx*. As almost all infective inflammations are of ascending type from coexisting uterine inflammation, the most severe changes and the obstruction in such cases are usually at or near the uterine end of the tube.

A common form of inflammation that results in hydrosalpinx in cattle is at least in part *traumatic in origin, following manual manipulation of the ovary*. Uterine irrigations are somewhat less important, but, in either event, it is the adhesion between the tube and adnexa (usually the ovary with partial or complete obliteration of the bursal cavity) that causes obstruction of the abdominal ostium and secondary hydrosalpinx. Squashing of the normal diestrual corpus luteum (there is at best only partial expression of the body) is not difficult but, because of its vascularity, there is always some hemorrhage, varying in extent from very slight to fatal. Small clots, which are usually retained in the bursa, can be completely resorbed. Larger clots must be organized, and this results in the formation of adhesions within the bursa and the fimbriated portion of the tube. With more extensive hemorrhage, adhesions may form to adjacent abdominal viscera and genital adnexa. Expression of pathologically persistent corpora lutea may result in little hemorrhage but a lot of tissue damage, and a more or less proportional degree of organization by fibrosis will result. The important types of persistent corpora lutea occur in association with pathological distension of the uterus. If this latter is pyometra, an additional complication is involved in that, as well as the manual trauma, there is liability to spillage of inflammatory products and extension of infection to traumatically devitalized tissue.

Therapeutic uterine irrigation in cattle, especially if performed in the early postpartum period, has also caused the type of adhesion referred to and follows one of two complications: the irrigation fluid may leak through the tube into the bursa and provoke an inflammatory reaction, the usual types of irrigating fluid being irritative, or the infusion of an excessive volume of fluid causes rupture of the uterus and perimetritis. Uteri vary in the amount of fluid they may retain, but any amount in excess of 120 mL is liable to cause uterine rupture, which occurs on the lesser curvature at the mesometrial attachment with permeation of fluid through or beneath the serosa. Inflammatory thickening is the usual result, and the development of serosal adhesions produces tubal obstruction and dilation.

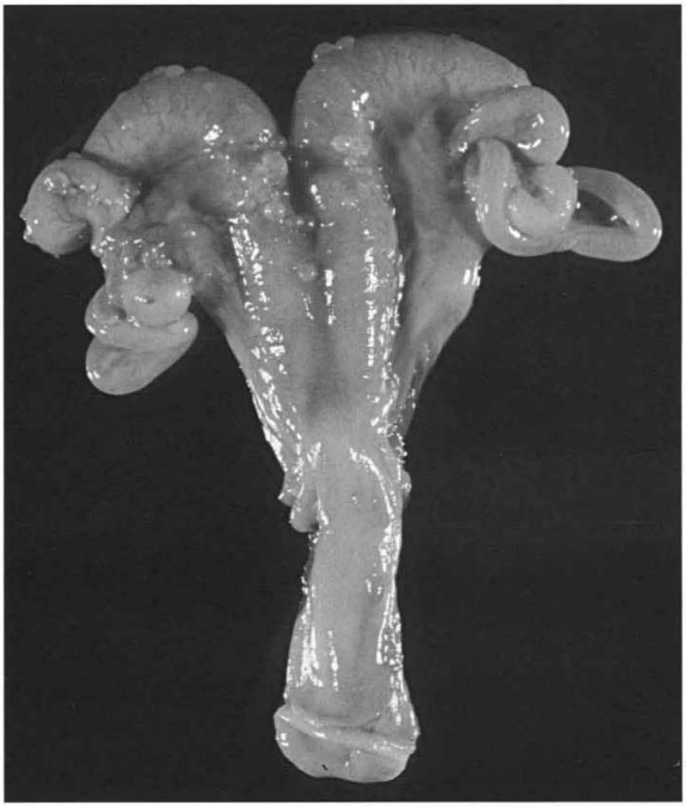

Figure 4.44 Bilateral hydrosalpinx in a sheep. There are also many serosal inclusion cysts on the surface of the uterine horns.

Salpingitis

The uterine tube is a rather simple structure histologically, but even minor inflammatory changes, evidenced by slight congestion or the presence of a few plasma cells, appear to be important because of the readiness with which the epithelial cells desquamate or lose their cilia. The proper function of the living epithelium is necessary for the propulsion of the ovum, for the dissolution of the cumulus oophorus prior to fertilization, and for the maintenance of a luminal environment suitable to survival of the ovum. The salpingeal mucosa has much less capacity for restitution than does the endometrium.

Inflammation of the uterine (fallopian) tubes without significant enlargement is the most common and most important tubal lesion. It is usually bilateral, is usually not detectable macroscopically, and may show serous, catarrhal, or fibrinous inflammation. In the mildest forms of salpingitis, the mucosa alone is affected and changes of functional significance may be slight enough to be overlooked histologically.

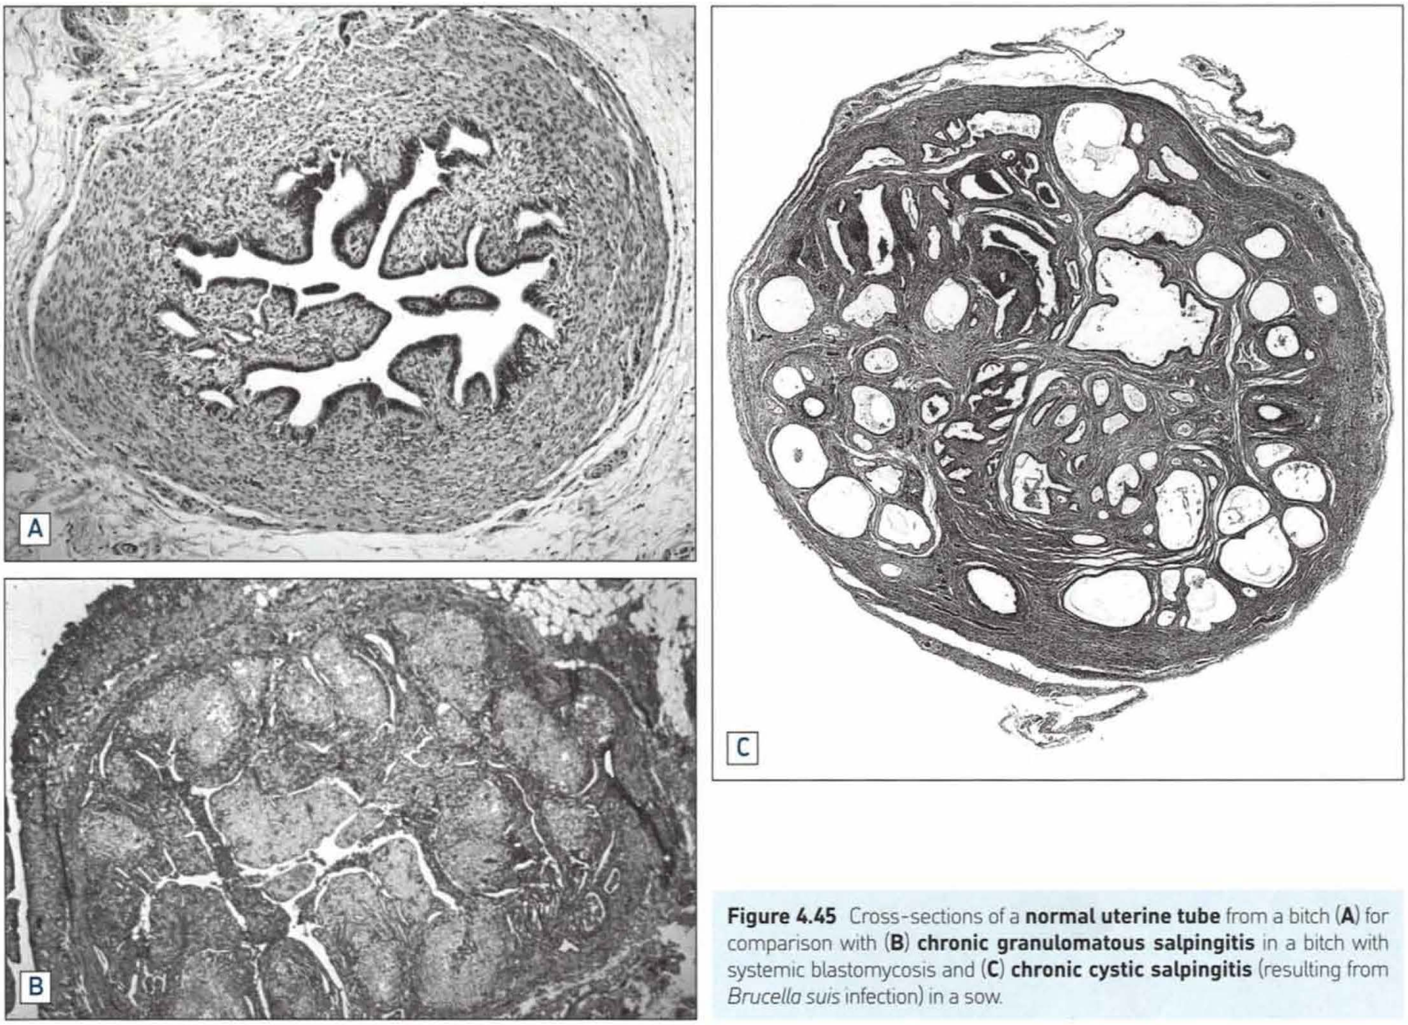

Figure 4.45 Cross-sections of a **normal uterine tube** from a bitch (**A**) for comparison with (**B**) **chronic granulomatous salpingitis** in a bitch with systemic blastomycosis and (**C**) **chronic cystic salpingitis** (resulting from *Brucella suis* infection) in a sow.

Congestion of the mucosal vessels, mononuclear-cell infiltration, loss of epithelial cilia, and some desquamation of epithelium may be the only changes detectable. With more severe infections, catarrhal exudate collects in the lumen, the mucosal folds are thickened by cellular infiltration and congestion, and the epithelium is in large part destroyed. Loss of epithelium occurs first in the free edges of the mucosal folds and these denuded areas tend to fuse and adhere to produce intramucosal cysts. Alternatively, in chronic catarrhal salpingitis, the mucosa is virtually destroyed and replaced by proliferated connective tissue and cellular infiltrations with more or less occlusion of the lumen (Fig. 4.45).

Salpingitis is a common lesion in animals, with both *Mycoplasma* and *Ureaplasma* infections. Nonspecific infections causing salpingitis almost invariably do so following spread from the uterus. *There is probably 70–75% association between uterine and salpingeal inflammation* when diagnosis of the latter is based on histological evidence. In some cases, there will be perimetritis with adhesions, pyosalpinx, or bursal abscess. *Adhesions* of the infundibulum of the mare are very common. The cause of these adhesions is unknown. Some are associated with perimetritis, but most are not. It has been suggested that they may develop as a result of ovulatory hemorrhage. However, this explanation does not easily account for the substantial predominance of adhesions of the right infundibulum.

Granulomatous salpingitis is uncommon. When it does occur, the uterine tube will be firm and distended (Fig. 4.45B).

Pyosalpinx

This is less common than hydrosalpinx, and typically follows metritis in the same manner as do other forms of salpingitis. *The significant anatomic difference is the accumulation of pus in the tube following obstruction of the lumen.* The obstruction may be produced by inspissated exudate, inflammatory thickening, and fusion of the mucosal folds, or chronic granulation tissue. The length of the tube is usually not uniformly involved by the inflammatory process; rather, there are segments in which the reaction is more acute or more advanced so that the obstruction tends to involve irregular segments with the intervening portions distended with exudate.

The entire thickness of the wall of the duct is infiltrated with neutrophils, lymphocytes, and plasma cells, and the same cells collect in the lumen and in the mucosal cysts formed by adhesions between the denuded epithelial folds. Surviving epithelium may be

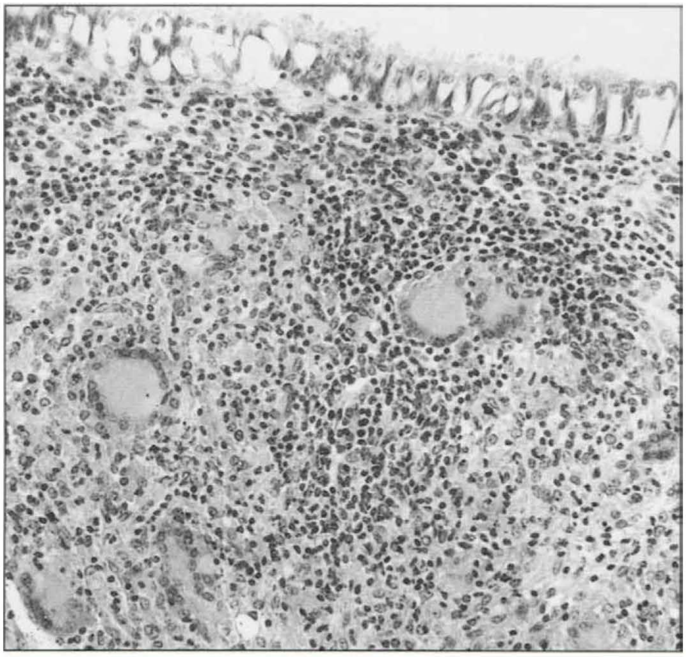

Figure 4.46 Granulomatous salpingitis from tuberculosis in a cow.

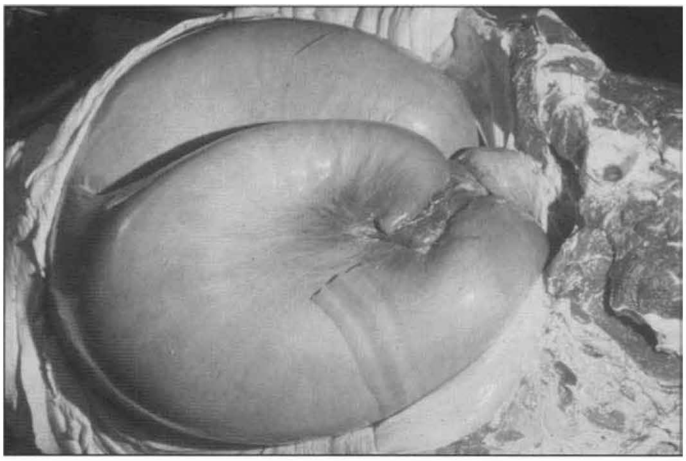

Figure 4.47 Uterine torsion in a cow.

partly squamous. Eventually, the bacteria will be destroyed and the exudate converted to a watery fluid (hydrosalpinx). Frequently accompanying pyosalpinx are the *bursal adhesions* and *local peritonitis* described earlier.

Among the organisms that may be found in inflammatory diseases of the uterine tube are streptococci, staphylococci, *Escherichia coli*, and *Arcanobacterium pyogenes*, with the latter as the most common and important. *Brucella suis* in swine and *Mycobacterium tuberculosis* in cattle are responsible for specific forms of salpingitis; the lesions are as described for these infections in the uterus (Figs 4.45C, 4.46).

PATHOLOGY OF THE UTERUS

Abnormalities of position or location

Torsion *of the uterus is uncommon except in the cow and mare.* In almost all cases, such twisted uteri are pregnant (Fig. 4.47), but torsion may also occur with pyometra and hydrometra. *The torsion is of the same nature as an intestinal volvulus and occurs about the transverse axis of the organ with the mesovarium as one fixed point.* In uniparous species (cow) in which a well-developed intercornual ligament does not permit much independent movement of the horns, the entire organ is involved in the torsion, which is about the mesovarium and vagina or cervix as fixed points. In multiparous species (bitch, cat) with long horns and no intercornual ligament, the torsion will involve part of one horn or the entire horn, the fixed points in the latter instance being the mesovarium and the site of attachment of the horn to the uterine body. There seem to be no rules governing the direction of the twist. Minor degrees of torsion (up to 90°) are fairly common in cows and apparently resolve themselves. *The condition becomes of importance only when the torsion is 180° or more and results in dystocia.* Any twist in excess of 180° may also result in local circulatory embarrassment. The thinner-walled veins are obstructed before the arteries, and the uterus becomes congested and edematous, with edema of the placenta and death of the fetus. The devitalized uterine wall becomes friable and susceptible to rupture or, if cesarean section is performed, the friability of the wall makes suturing difficult. Death of the fetus may be followed by mummification if the cervix remains closed; if air and infection enter the uterus, the fetus putrefies. In the bitch and cat, transverse rupture of the twisted segment near parturition can release the dead fetuses into the peritoneal cavity (Fig. 4.48).

The fetuses that escape into the peritoneal cavity undergo mummification, attach to the omentum, liver, or intestine, and become covered by a rather thin membrane. Occasionally, a fetus becomes dismembered and fetal bones may be scattered throughout the omentum. In some cases, the mummified fetuses remain in the peritoneal cavity for months or years without causing clinical signs of disease. If the horn does not rupture, the fetus may die, become mummified, and the uterine tube will shrink in size (Fig. 4.49).

Prolapse *of the uterus occurs fairly commonly in ruminants*, exceptionally in other species. Predisposing causes in the cow are essentially those that cause, or are associated with, uterine hypotony and probably also with dysrhythmia of involutionary contractions. Amongst the most common associations in the cow are *prolonged dystocia relieved by forced traction, retained placenta, and postparturient hypocalcemia.* Probably the same sort of influences operate in ewes and, in addition, uterine prolapse after parturition is a common complication of the *hyperestrogenism* which results from the ingestion of legumes with a high content of estrogens.

In any species, usually only the previously gravid horn prolapses. In the cow and ewe, the nongravid horn, and sometimes intestine and bladder also, may be present within the everted horn. The pathologic sequelae of prolapse are comparable to those of intestinal intussusception with the added factor of trauma. Congestion and edema are followed by hemorrhage, necrosis, and sepsis. Gangrene may supervene.

Rupture of the uterus may occur spontaneously, but is usually a result of *obstetrical manipulations.* Most ruptures occur in the fundus adjacent to the pelvic brim as irregular tears that may involve

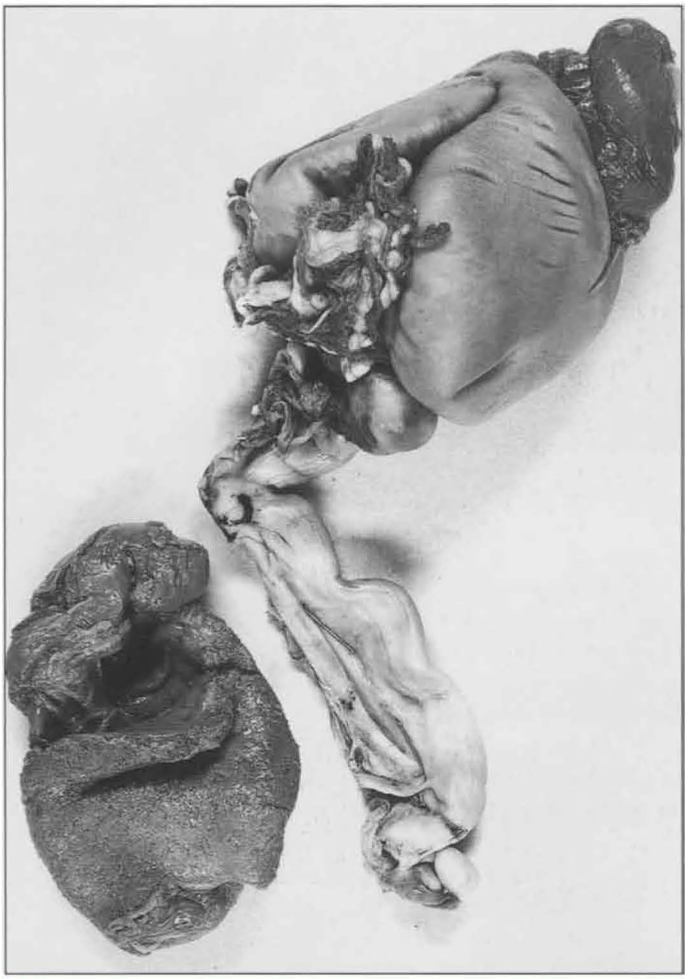

Figure 4.48 Uterine torsion and rupture in a bitch with release of a fetus and placenta into the abdominal cavity.

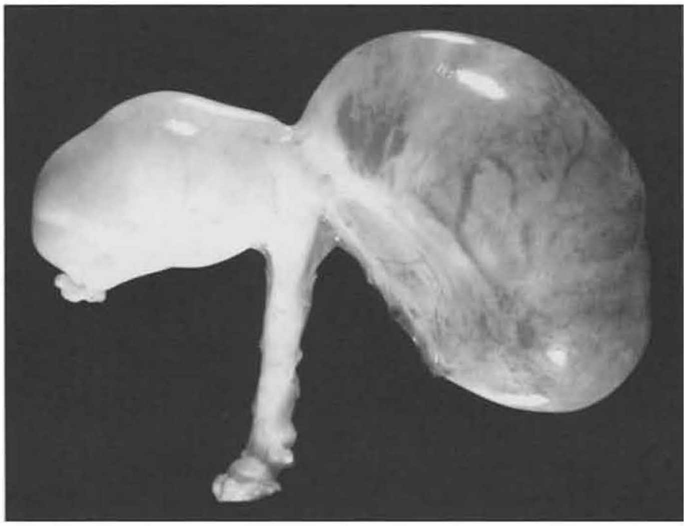

Figure 4.49 Uterine torsion of a gravid uterine horn in a cat.

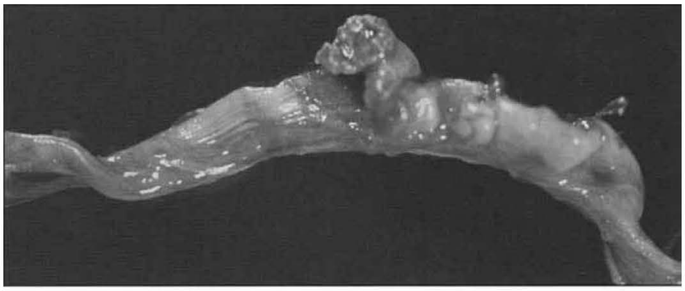

Figure 4.50 Uterine artery rupture in a mare. The resulting hematoma can dissect along fascial planes in the broad ligament, or extend into the abdominal cavity where they continue to bleed and may lead to exsanguination.

the full width of the wall or only the mucosa. Mucosal ruptures are of little consequence. Complete ruptures are often fatal either by virtue of hemorrhage, or spread of uterine inflammation to the peritoneum, or displacement of retained membranes into the abdominal cavity. The majority of ruptures occur in uteri that are devitalized as a result of torsion or prolonged dystocia.

Rupture may also follow acute distension of the uterus produced by *infusion fluids*. This is not an uncommon accident. The rupture occurs on the lesser curvature along the line of attachment of the mesometrium, and the irrigating fluids spread into the ligament.

Circulatory disturbances

Endometrial hyperemia and edema occur normally at *estrus* and reach the greatest relative development in the bitch in proestrus. The resulting diapedesis and endometrial exfoliation account for the uterine hemorrhage at proestrus in this species. A small amount of mucosal hemorrhage is common in heifers, less common in older cows, and occurs immediately after estrus. The source of the hemorrhage is the endometrial capillary bed immediately cranial to the cervix. It is probably an estrogen-withdrawal effect and the nearest thing to menstruation in domestic animals. Punctate hemorrhages occur in the uterine serosa in heifers in estrus.

Hemorrhage of pathologic import follows *torsion and inversion*, by obvious mechanisms. Perhaps the most common association of abnormal bleeding is *endometrial hyperplasia* in the bitch, especially if there is superimposed infection. A less common cause in this species is the *uterine fibroleiomyoma* (fibroid). Vaginal hemorrhage from uterine leiomyosarcomas was a fairly common clinical feature in Saanen goats.

Rupture of the uterine artery with hemorrhage into the broad ligament, with or without extension into the abdominal cavity, occurs in the mare. The latter situation commonly results in the death of the mare from exsanguination. The uterine artery near the rupture commonly contains chronic degenerative changes (Fig. 4.50).

PATHOLOGY OF THE ENDOMETRIUM

Irregularities of endometrial growth

Atrophy

Atrophy of the endometrium results from loss of trophic ovarian function. Senile atrophy is not important in large domestic animals. Atrophy is common after ovariectomy, but may reflect hypopituitarism of chronic inanition or wasting disease, or a primary hypophyseal lesion. The more superficial portions of the endometrium are the more atrophic and, in advanced atrophy, the lining mucosa covers a thin layer of condensed stroma in the depths of which are the inactive glandular remnants that are sometimes cystic.

The endometrium of those species that have a seasonal period of anestrus undergoes a normal atrophic change. In mares, in which these changes have been studied by endometrial biopsies, the luminal and glandular epithelium may become cuboidal and the glands are straight during the winter anestrous period, but there is considerable individual variation in the degree of atrophy mares develop.

Hyperplasia

General considerations

Endometrial hyperplasia in the bitch is common and usually involves cystic distension of endometrial glands. The condition is called **cystic endometrial hyperplasia** and, if extensive, results in accumulation of endometrial secretions in the uterine lumen. In turn, infection of the uterus may follow. This association has led to the sequence of endometrial hyperplasia and subsequent infection being known as the *cystic endometrial hyperplasia–pyometra syndrome.*

Experimental studies have shown that a variety of *sterile substances*, such as sterile silk or autogenous tissue, when placed in the lumen of the uterus of a bitch in the luteal phase of the estrous cycle, will result in dramatic endometrial proliferation and remodeling. These studies demonstrated how sensitive and responsive the canine endometrium is during the period of the estrous cycle when it would be an intimate part of placental structures if the bitch were pregnant. *Bacteria* might also provide appropriate stimulation that could drive the endometrium to undergo hyperplasia and hypertrophy. An alternative plausible pathogenesis for cystic endometrial hyperplasia–pyometra is that an initial event is the establishment of a *low-grade, subclinical infection* that during the luteal phase (also referred to as the secretory or progestational phase) causes the endometrium to proliferate. Changes in the uterine environment, accumulation of secretions, and other progestational effects could then lead to massive proliferation of bacteria and inflammatory cellular infiltration into the endometrium with accumulation of purulent exudate in the uterine lumen.

Cystic endometrial hyperplasia can involve either a single or a few glands, or endometrial glands extending along segments of endometrium (Fig. 4.51). Sometimes, the entire endometrial surface is involved. Individual endometrial glandular cysts can become quite large, up to 1 cm. More diffuse involvement can leave the endometrium thickened and, on cross-section, effaced by variably dilated glands (Fig. 4.51C, D).

Endometrial hyperplasia can also be attributed in some species to *excessive and prolonged estrogenic stimulation*. Sources of estrogen can be endogenous, for example from granulosa cell tumor, or exogenous, as in ingestion of certain plants. Secretions from a markedly chronically stimulated endometrium can lead to gross accumulation of mucoid fluid in the uterus, a condition called *mucometra* (Fig. 4.52).

Progesterone has been shown to play the major role in the induction of endometrial hyperplasia in the dog and cat, but even here the endometrial response to progesterone depends upon *estrogen priming*. Estrogens act by binding to the estrogen receptors that are

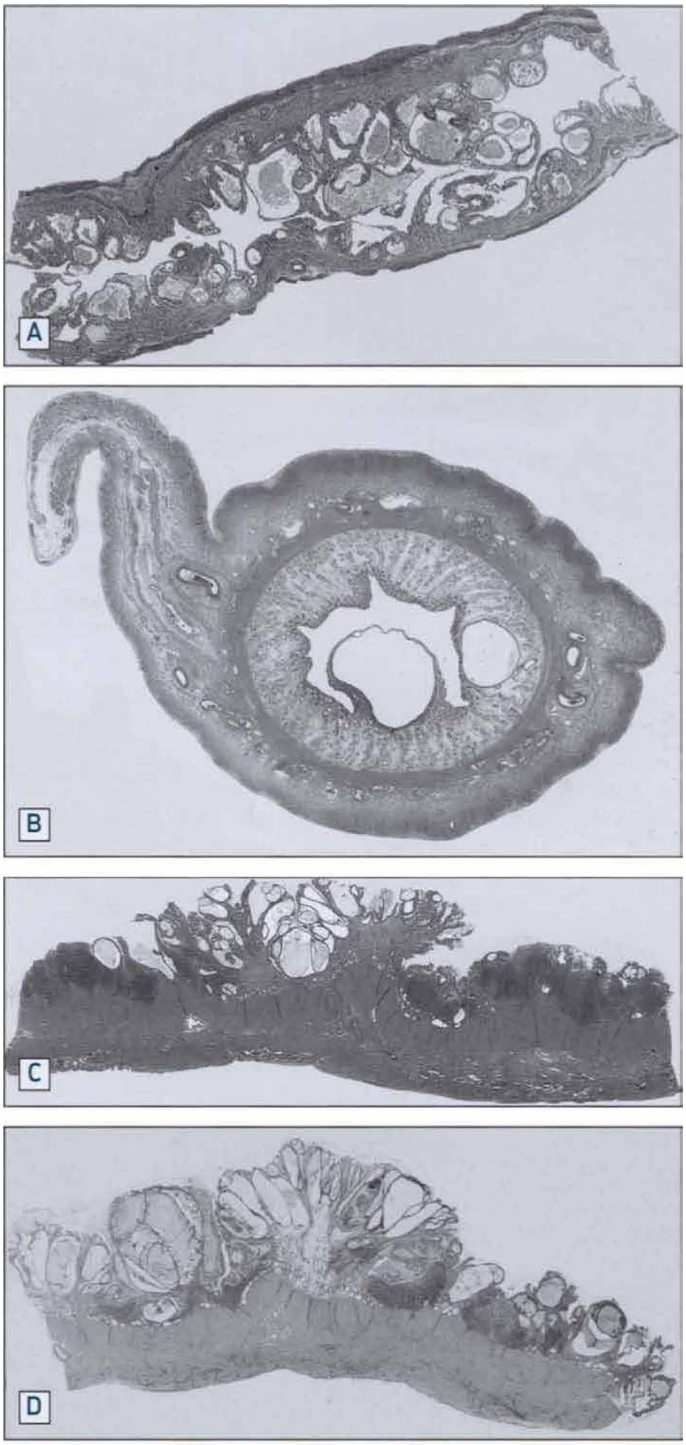

Figure 4.51 A–D Cystic endometrial hyperplasia in uterine sections from four bitches. The hyperplasia can involve one or a few glandular units (upper panel), or have a much more diffuse, locally extensive involvement. Occasionally, the entire endometrium is involved. The hyperplastic endometrium in the latter cases tends to secrete large amounts of fluid. The darker areas in the endometrium in the lower photographs are mononuclear cellular infiltrates that become neutrophilic in response to secondary bacterial proliferation. *The neutrophilic exudate and endometrial hyperplasia are characteristic features of pyometra.*

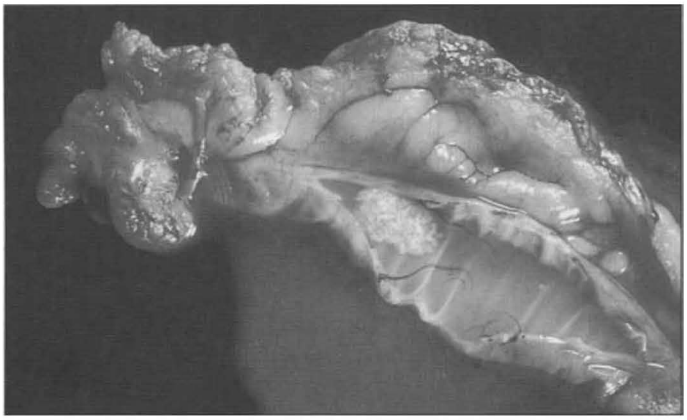

Figure 4.52 Mucometra distending the uterus of a bitch. The physical pressure placed on the endometrium can lead to endometrial atrophy over time.

present in the endometrial cells and act on these susceptible cells to induce the synthesis of intracellular receptors for progesterone. The progestational effect of conversion of the endometrium to its secretory mode depends on this estrogenic priming, and it is likely that in some cases the disturbances of endometrial growth giving rise to endometrial hyperplasia are to be found in the disturbances of the timing and duration of the priming, although cystic endometrial hyperplasia can be produced in the bitch in the normal early-diestral uterus by mild trauma (see also section on Pyometra, in the bitch and queen, below). Many cases of cystic hyperplasia of the endometrium have developed following the use of long-acting progestational compounds to delay the onset of estrus in bitches. Cystic endometrial hyperplasia in the *cow* is associated with ovarian follicular cysts or granulosa-cell tumors, both of which can produce prolonged hyperestrogenism. Cystic endometrial hyperplasia is very uncommon in the *mare*. It has not been associated with granulosa-theca cell tumors in this species.

Ovarian tumors, especially granulosa theca-cell and papillary cystadenocarcinomas, are present in some cases of endometrial hyperplasia of the bitch, but in the majority of clinically recognizable cases, the ovaries contain apparently normal corpora lutea. The hyperplasia develops during the long luteal phase that is normal in the bitch. Often paraovarian cysts are present in cases of endometrial hyperplasia.

Noncystic endometrial hyperplasia is not recognizable macroscopically except as an equivocal thickening of the endometrium. The thickening is due to increased size and number of glands, which are irregular in their distribution and course, the normal parallel alignment being lost. The stroma is not hyperplastic but is edematous. The glands may show both proliferative and secretory activity. In the bitch, the glands are tortuous and secretory; the mucosal epithelial cells are typically progestational, being hypertrophied with clear cytoplasm; the glands of the basal endometrium are also active; and there is little evidence of the normal partitioning of the endometrium into layers. There is usually some degree of adenomyosis. Cystic hyperplasia, the so-called "Swiss-cheese" endometrium, is the histologic extreme of the condition and is irreversible. *It is probable that endometrial hyperplasia is but an exaggeration of the normal proliferative activity of the endometrium in response to ovarian hormones.*

Endometrial hyperplasia is a significant precancerous lesion in women. In domestic animals, this is not so. Endometrial hyperplasia is very common in the bitch but uterine cancer is extremely rare.

Canine segmental hyperplasia

The endometrium of the bitch occasionally undergoes an unusual, but very characteristic, endometrial segmental hyperplasia consisting of localized proliferation of the endometrial glands and endometrial surface that *closely resembles pregnancy implantation sites* (Fig. 4.53). The unopened uterus may have one or more ovoid distended areas that may resemble pregnancy sites. Prior to opening the uterus, other differential diagnoses would include endometrial polyp, chronic pyometra, leiomyoma, or fetal mummification.

Segmental endometrial hyperplasia can occur in virgin bitches, but they may also represent persistence of endometrial remodeling at sites where an embryo has been lost. Similar segmental areas of hyperplasia have been experimentally produced by placing various sterile materials in the lumen of bitches that are in the luteal phase of their cycles. It has been suggested that these are florid decidual reactions, and have been referred to as *deciduomas*, but use of this term is discouraged.

The microscopic features are characteristic (Fig. 4.54). The hyperplastic endometrium may appear as a broad-based polypoid mass extending into the uterine lumen (Fig. 4.53A), or may form a continuous band of protruding tissue (Fig. 4.54A). The endometrium is organized in three discrete layers, corresponding to the deep glandular zone, condensed connective tissue band, and folded luminal epithelial junctional zones. The luminal surface is always necrotic, and no fetal placental tissues are found.

Estrogenic plants

Pasture legumes as sources of estrogenic activity have claimed attention as a cause of a spectacular syndrome of *infertility in* **sheep**, and as a cause of less obvious depression of fertility in sheep. Although many estrogenic substances are known to occur in plants, pasture plants that have been found to produce estrogenic effects are mainly some varieties of *Trifolium subterraneum, T. pratense, Medicago sativa,* and *M. truncatula*. The estrogens of the clover species are usually *isoflavones*; alfalfa and the barrel medic contain *coumestans*.

Extensive metabolism of phytoestrogens occurs in the rumen. During such metabolism, compounds of very different estrogenic potency from those in the plant can be produced. Among the isoflavones, formononetin, a compound with little estrogenic activity in itself, is the main compound producing histologic effects in sheep after its conversion in the rumen to the potent estrogenic metabolite, equol.

There is variation in estrogenic potency between strains of clover and also with the season or stage of growth, activity being greatest in winter and early spring. Potency is diminished if the clover is allowed to wilt and dry, or if it is made into hay, but the activity is retained if the clover is artificially dried.

Estrogenic pastures grazed during the breeding season may temporarily impair fertility, and ewes so affected may have a very low lambing rate and a high incidence of dystocia and uterine prolapse. Wethers on such pastures develop enlargement of the bulbourethral glands (see Vol. 3, Male genital system). The fertility of affected ewes

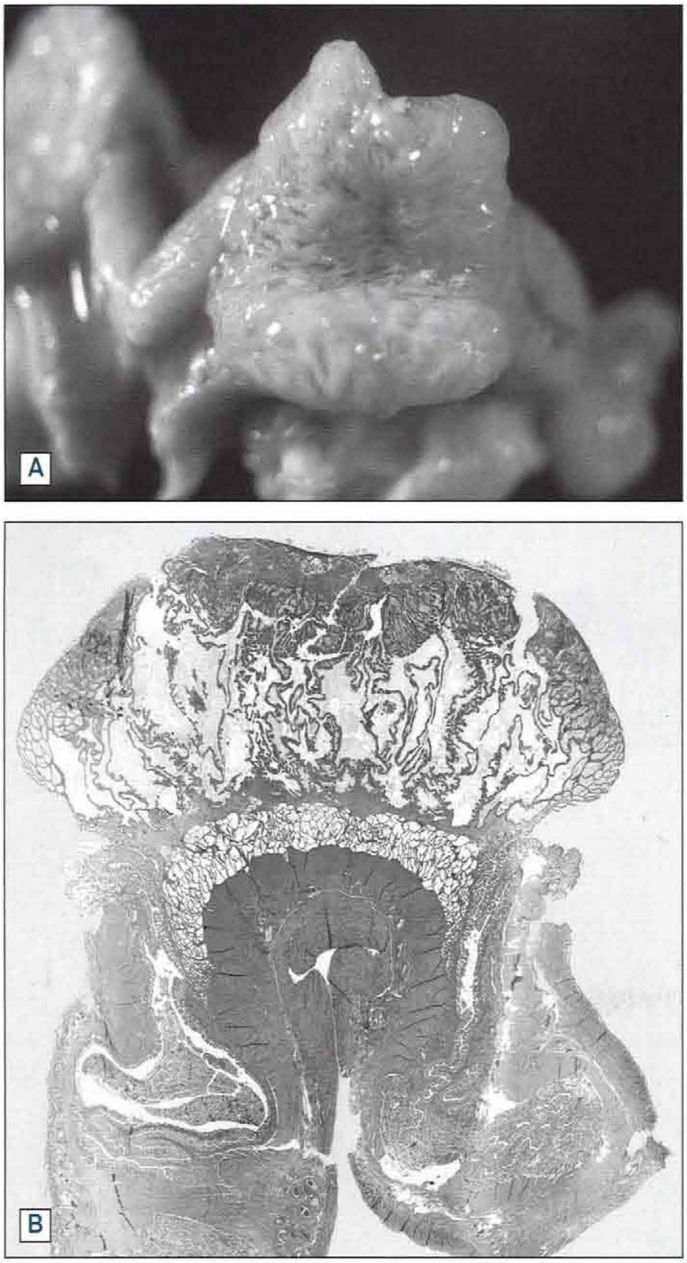

Figure 4.53 A, B. Segmental endometrial hyperplasia in a bitch. A less common form of endometrial hyperplasia occurs during the luteal phase in some bitches. The endometrium along one or more discrete sections of the uterine horn undergoes a highly organized hyperplasia that is very similar to the endometrial tissue remodeling that occurs at placentation sites during normal pregnancy. The uterine horn is distended and, when cut open, the proliferative band of endometrial tissue protrudes from the endometrial surface.

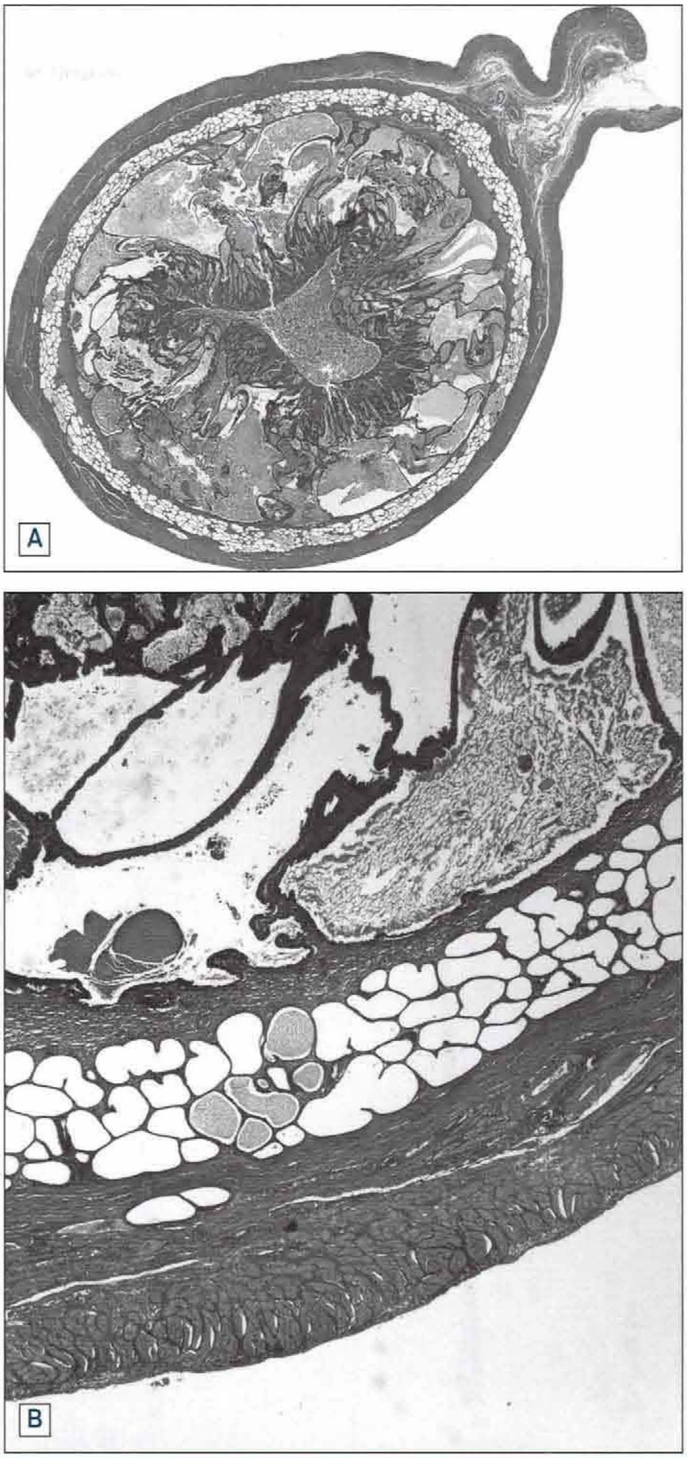

Figure 4.54 Subgross photograph of **segmental endometrial hyperplasia** in the bitch. Note the uniform distension of the deeper areas of endometrial glands. The luminal epithelium has many thin folds, lined by secretory epithelial cells. The luminal aspects of these folds are usually necrotic and the necrotic debris is admixed with mucoid endometrial secretions. The subgross photograph in (**A**) is a section of uterine horn cut through the center of one of these areas. Panel (**B**) is a higher magnification of the deep glandular area with a thin band of tissue separating the highly proliferative villous folds that resemble the junctional zone that develops in normal canine placentation beneath the area of zonary attachment.

is returned after removal from the offending pastures. The infertility is in large part attributable to failure of transport of sperm through the cervix due to changes in the cervical mucus. Estral cycles are normal, and normal ovulation apparently occurs. The dystocia that is common is attributed to reduced myometrial tone at parturition; it results in a high rate of maternal and neonatal death. Uterine prolapse occurs in maiden and nonpregnant ewes as well as postpartum ewes; mammary development and lactation occur in nonpregnant ewes.

The principal morphologic changes in the cervices of affected ewes consist of greater glandular development, reduced numbers of goblet cells, and a reduced amount of stratified epithelium. These changes are associated with an increased incidence of cervicitis. The endometrium is hyperplastic, and macroscopic cysts are often present. Hydrometra and pyometra are occasionally seen. These are the signs and lesions that were described in the original reports of infertility in ewes caused by estrogenic plants, commonly known as *clover disease.*

The development of varieties of clover low in formononetin has made it possible through changes in management and agronomic measures to control the most severe forms of the disease. But, as the original syndrome has been brought under control, *a much more insidious form of estrogenic infertility in ewes has emerged as the result of chronic or repeated ingestion of low levels of phytoestrogens.* This syndrome causes less severe reproductive losses, but the infertility tends to be permanent. Its anatomic basis consists primarily of subtle cervical changes that also impair sperm transport. The cervical lesions are those of blunting of the cervical folds with a reduction of the number of folds and crypts associated with an increase in the stroma of the lamina propria. There is an increase in coiled tubular glands of the endometrial type in the cervical lamina propria. This change is most severe at the cranial end of the cervix. This glandular induction is the reason the disease has been referred to by the awkward name of *estrogen-induced transdifferentiation.* The persistent effects of estrogen also bring about modification of sexual behavior; some ewes develop a more male behavior, clitoromegaly, and fusion of the ventral labia. These changes are mild and the disease can be best identified by careful cervical histologic examination, determining the number of folds and quantifying the area of the lamina propria. Since this is unknown territory for most pathologists, adequate control material is essential.

The effects of estrogenic pastures or of the various isoflavones on **cows** have not been conclusively examined, but there is little doubt from information accrued in Israel and Tasmania that the effects are important; alfalfa (lucerne) and the clovers listed above have been blamed. The principal features of the syndromes reported are similar to those produced by cystic follicles. The infertility rate is high and is associated with persistent cystic ovaries, aberrations of the estrous cycle with abnormally long estrus, swelling of the vulva independent of estrus, and sometimes enlargement of the clitoris, increase in size of the uterus and cervix with cystic endometrial hyperplasia, and enlargement and function of the virgin mammary gland.

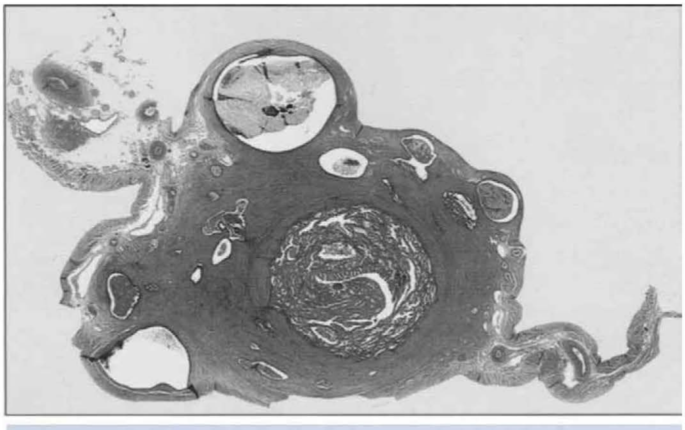

Figure 4.55 Canine adenomyosis. Adenomyosis can appear as single small gland profiles within the myometrium, or become marked, as demonstrated in this subgross section. Variably sized cystic endometrial glands are scattered throughout the myometrium and protrude from the serosal surface of this cross-section of uterine body. The epithelial lining of these ectopic glands ranges from normal-appearing (see Fig. 4.56) to attenuated in the larger cysts.

Adenomyosis

This term applies to the presence of endometrial glands and stroma between the muscle bundles of myometrium (Figs 4.55, 4.56).

In some cases it is a malformation and in others it arises by hyperplastic overgrowth of the endometrium. It is not a common lesion in any domestic species, but is seen in the bitch with cystic endometrial hyperplasia. Adenomyosis is occasionally observed in cows as part of the local disarray of segmental aplasia. It may also be present as a malformation of the tips of the uterine horns in cows.

Adenomyosis as seen in domestic animals shares features with *endometriosis* of menstruating primates. However, there are important

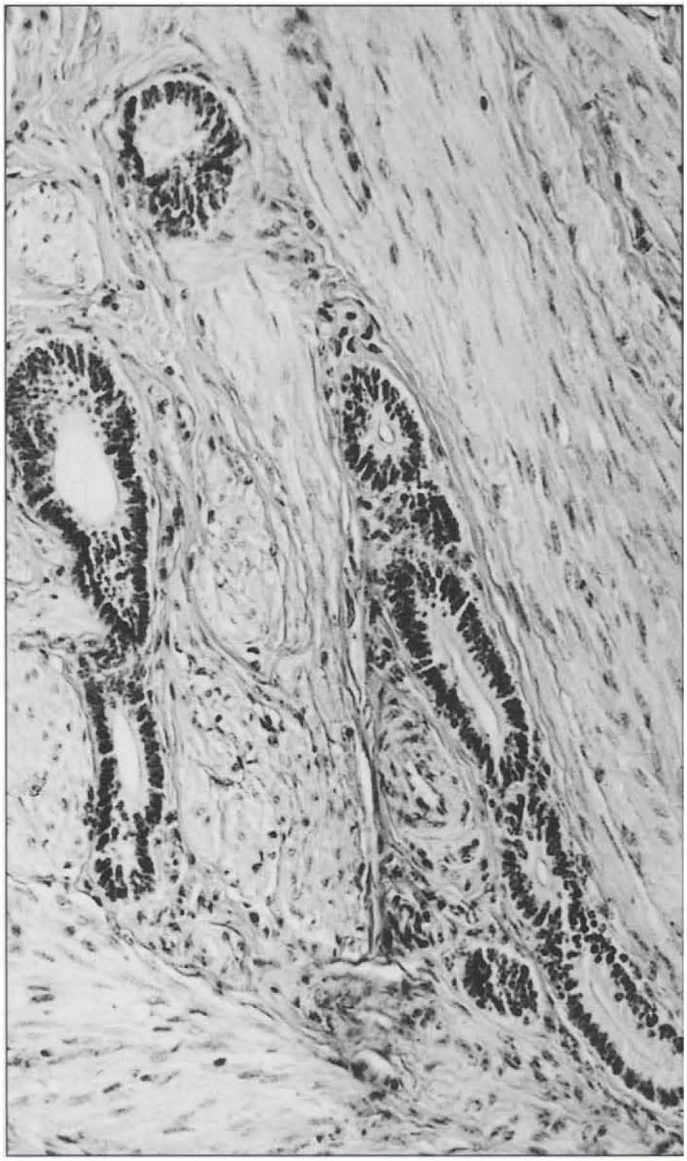

Figure 4.56 Photomicrograph of **canine adenomyosis**. These slightly irregular endometrial glands are present within the myometrium.

distinctions. Endometriosis is a condition in which actively growing endometrial tissues are explanted to aberrant sites within and outside the uterus. One of the aberrant sites can be the myometrium; in this site the two conditions are histologically similar.

Endometrial polyp

This lesion is seen most commonly in the bitch and queen and is striking when the polyps are large (Fig. 4.57). Segmental distension of the uterine horn(s) can be confused with tumors of the myometrium (leiomyomas), chronic pyometra, pregnancy or sites of fetal resorption, or segmental cystic endometrial hyperplasia. In contrast to the polypoid form of endometrial hyperplasia, *the true polyp contains substantial connective tissue stroma in addition to dilated glands, and is pedunculated* (Fig. 4.58). Polyps may be multiple or isolated, and their shape is molded to the uterine lumen.

Polyps may provide sufficient mass that uterine contractions can mechanically force prolapse of the affected horn. Endometrial polyps may be observed protruding through the cervix into, and sometimes even from, the vagina.

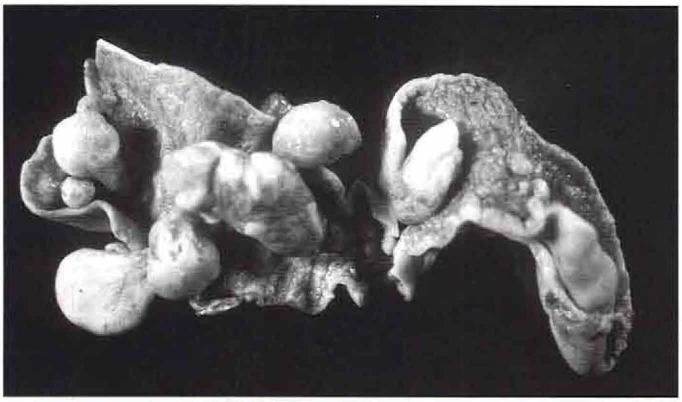

Figure 4.57 Multiple **endometrial polyps** in a queen. This queen had several firm segmental enlargements involving both uterine horns. Endometrial polyps can be single or multiple and occur most commonly in older queens and bitches.

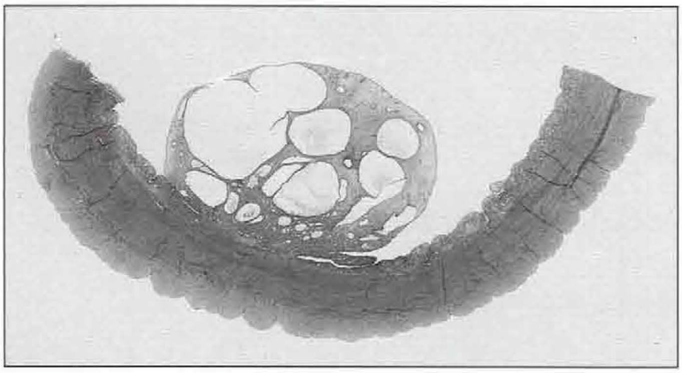

Figure 4.58 Canine **endometrial polyp** extending into the uterine lumen. Note the cystic spaces that are dilated endometrial glands. These polyps contain fibrous connective tissue bands, and progress from locally extensive areas of cystic hyperplasia that become fibrotic, compromising release of secretions from the glands. With uterine contractions and limitation by the lumen, these become pedunculated. Larger polyps assume the shape of the lumen and can become fusiform.

Uterine accumulation of secretory or inflammatory exudates

Hydrometra and mucometra

The two conditions are considered together as the difference is probably only in physical properties and depends on the degree of hydration of the mucin, which in turn may be related to the relative activity of estrogenic hormone. *The accumulation of thin or viscid fluid in the uterus is concurrent with the development of endometrial hyperplasia or is proximal to an obstruction of the lumen of the uterus, cervix, or vagina.* Grossly, there is uniform distension of the uterus (Fig. 4.59). If hydrometra or mucometra persists for a long time, the endometrium becomes markedly attenuated and will atrophy (Fig. 4.60).

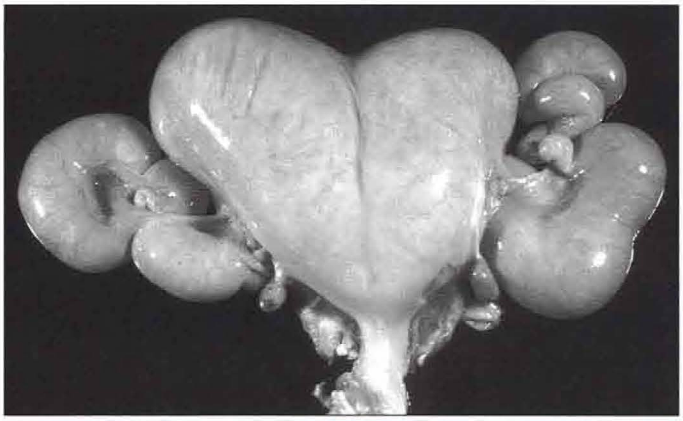

Figure 4.59 **Hydrometra** in a goat. The uterine wall becomes thinner as fluids accumulate. Accumulation of viscous fluid within the uterus is called *mucometra*.

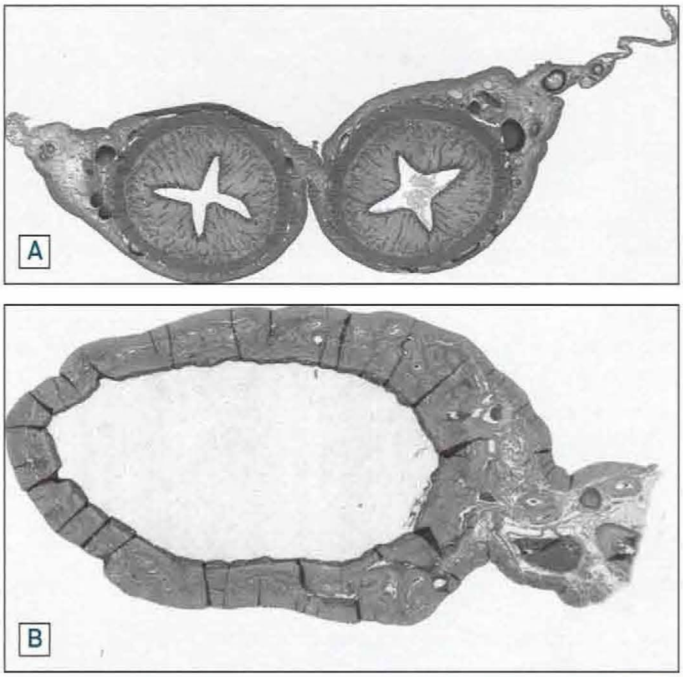

Figure 4.60 **A.** Subgross photograph of a cross-section of normal uterine horns from a bitch for comparison to the distended uterine lumen from a bitch with **hydrometra** in (**B**). Long-standing hydrometra or mucometra can lead to atrophy of the endometrium.

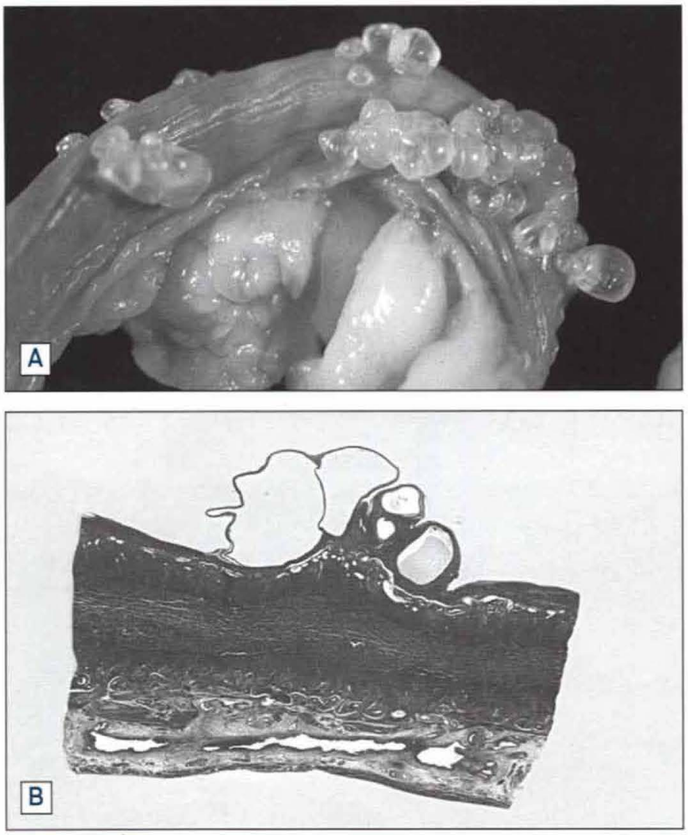

Figure 4.61 A. Serosal inclusion cysts on the surface of a uterine horn from a bitch. These cysts develop following adhesion of the serosa to itself in areas of linear folds and, most likely, in association with mild or minimal perimetritis. No inflammation is present by the time the cysts are detected. **B.** Cysts are most commonly multiple, thin-walled, and contain clear fluid, as shown in this subgross photograph taken from tissues from a different bitch. They can be differentiated from mesonephric duct cysts that are only found at the attachment of the mesometrium (broad ligament) and are usually single or tubular. They also occur in other species, but are most commonly found in older multiparous bitches and small ruminants.

In cases of congenital or acquired obstruction of the lumen of the tubular genitalia, the volume of fluid that accumulates proximal to the obstruction depends on the site of the obstruction. In uterus unicornis, there may be 500 mL; in imperforate hymen, there may be 10 L or more. The fluid is slightly cloudy and watery but, in some cases of segmental aplasia where the volume of retained secretion is not great, it may be very viscid, ocher-colored, and sometimes inspissated to rubbery masses of mucin and cellular detritus (see Fig. 4.21). In these cows, the ovaries are normal. If affected uteri become infected, an intractable pyometra results. An abnormally long and tortuous cervix may result in a form of mucometra caused by the retention of uterine secretions.

Serosal inclusion cysts

Uterine serosal inclusion cysts are thought to arise by pinching off of surface epithelial indentations. They are occasionally observed in the aged pluriparous bitch and less commonly in ruminants, and appear as thin-walled cysts containing clear watery fluid and vary in size from a few millimeters to several centimeters. Serosal inclusion cysts form from small folds of peritoneum that adhere and form entrapped pieces of serosal epithelium that slowly accumulate secreted fluids. They tend to occur either during uterine involution or in association with perimetritis; however, inflammatory cellular infiltrates are not usually present in or near these cysts. The gross appearance of these cysts can be striking. Most lie on the surface of the uterus (see Figs 4.44, 4.61). They contain clear fluid and have thin translucent walls. They may vary from a few millimeters to 2 cm or more in diameter. Serosal inclusion cysts can be distinguished from paraovarian cysts by their location. Similarly, although a differential diagnosis would also include mesonephric duct cyst, the latter are located along the broad ligamentous attachment, tend not to be multiple, are not as superficially located, and microscopically would have smooth muscle in their wall.

INFLAMMATORY DISEASES OF THE UTERUS

General considerations

Inflammation limited in extent to the endometrium is termed **endometritis**; involvement of the entire thickness of the wall is **metritis**; of the serosa, **perimetritis**; and of the suspensory ligaments, **parametritis**. The classification is to some extent a useful index of the severity of reaction and of the pathogenesis. The great majority of inflammatory conditions of the uterus begin in the endometrium and are in some manner associated with the reproductive process. The predisposing factors are to be sought then at either end of the gestation period.

The normal nonpregnant uterus is endowed with a high degree of resistance to infection, and even in the case of the specific genital diseases, brucellosis, trichomoniasis, and *Campylobacter* infection, is incapable of supporting bacterial growth or even the persistence of bacteria for any extended period. Something is known of factors that render the uterus susceptible, at least temporarily, to infection, but little is known of the mechanisms of its resistance. The self-limiting nature of most infections, other than those associated with pyometra, has long been recognized and formed the basis for the recommendation of a period of sexual rest for animals with uterine infections. Even the specific genital infections are self-limited in duration; active infection of a uterus with *Campylobacter fetus* or *Tritrichomonas foetus,* in the absence of pregnancy, survives only for two to three estrual cycles. *Brucella abortus* causes infection of the pregnant uterus but does not persist well in the nonpregnant uterus, although it is apparently capable of persisting in the mammary gland and lymph nodes of infected cows. *Uterine resistance varies during the estrous cycle, susceptibility being greatest during the luteal phase of the cycle.* Several factors may be involved. Uterine motility is increased during estrus and this aids in the physical clearance of microorganisms. Uterine synthesis and secretion of immunoglobulin G (IgG) and IgA vary somewhat during the cycle, but the variations are not great and the timing varies between species. The functional activity of the polymorphonuclear leukocytes migrating into the uterus may also be affected by the stage of the cycle, being more active during estrus than diestrus, but much of the reduced uterine resistance during diestrus and pregnancy is related to secretion into the uterine lumen of progesterone-induced immunosuppressants that are capable of inhibiting lymphocyte proliferation. It has been well demonstrated that *the uterus that is under the influence of progesterone (which includes the pregnant uterus) is very susceptible to many nonspecific bacteria*, and that a uterus not under the influence of progesterone is remarkably resistant to the same organism, even when its expulsion is prevented by ligation of the cervix. This comparison can be carried a step further to show that even greater susceptibility to infection is present at the implantation sites in the pregnant uterus. The uterus of the castrate is resistant to infection but does not clear infections as promptly as does the uterus under the influence of estrogens. These factors of susceptibility and resistance provide some insight into the pathogenesis of postcoital uterine infections and pyometra in the dog and cat.

A different set of influences operates on the puerperium. *It is well recognized that uterine infections are likely to follow any abnormal parturition, such as an abortion, retained placenta, twin births, dystocia, and traumatic lacerations of the genital canal.* Of the specific abortive agents in the cow, *C. fetus* and *T. foetus* typically cause early death of the conceptus that is not complicated by placental retention or metritis. But with other causes, *B. abortus* especially, abortion may occur later in pregnancy, at which time the well-developed and manifold interdigitations of the cotyledons favor retention of the placenta and the development of acute metritis. But in these instances much of the uterine disease is the result of secondary invasion by bacteria that gain access to the uterus as the result of an abnormal delivery of a dead or diseased fetus.

Some cases of postpartum metritis are a continuation and exaggeration of a gestational uterine infection, but *most puerperal infections of the uterus can be viewed as analogous to wound infections, with the organisms entering via the cervix.* Probably all mares have uterine infections by streptococci within 1–3 days of parturition, but these do not persist for more than 2–3 days. In the cow, too, it has been observed that 25–30% are infected in the normal puerperium but that most recover spontaneously from these infections with *Arcanobacterium pyogenes, Escherichia coli,* and other bacterial mixtures. Clearly, the outcome will be determined as much by the number and virulence of invading organisms as by the environment within the uterus. The recognized predisposing causes outlined above will all be associated with retarded uterine involution, as will most cases of metritis. With the more virulent anaerobic bacteria, such predisposition is not essential.

The period necessary for normal involution varies with the species and is determined by the nature of placentation (depth and nature of invasion – deciduate versus adeciduate) and the rate of endometrial repair. It is well advanced in the mare within 9 days, as judged by the capacity for fertile mating at that time, in contrast to the involutionary process in the bitch, which involves deposition of material and extensive, slowly progressive remodeling. In the latter case, abnormalities of involution are common and termed *subinvolution of placental sites*. Most of these are probably never recognized clinically and spontaneously regress.

Endometritis

In endometritis, *the endometrium or uterine mucosa is mainly involved.* Almost all uterine infections begin as endometritis, and many such cases progress to involve the myometrium, becoming metritis. The mildest forms are seen postcoitus. In the mare, semen is ejaculated directly into the uterus and induces a transient postcoital endometritis. Infectious agents tropic for the uterus include *T. foetus* and *C. fetus* or pyogenic cocci and coliforms of low pathogenicity.

Uterine infection frequently occurs in **mares** both following foaling and after coitus by α-hemolytic streptococci, *Klebsiella pneumoniae, Escherichia coli* and *Taylorella equigenitalis,* the contagious equine metritis organism. The endometritis is usually mild, but the impact on fertility can be substantial.

Mild endometritis may not be overtly evident clinically. A slight opacity of the normally crystal-clear estrual mucus may be all that is seen. Histologically, the changes are not striking and consist for the most part of a diffuse but light infiltration of inflammatory cells with slight desquamation of the superficial epithelium and no significant vascular changes. Involvement of the glands is minimal. The significance of a few leukocytes in the stroma is always equivocal in cattle; they follow within 2–3 days of parturition and are present during estrus. However, the presence of neutrophils in the stroma of the endometrium is evidence of inflammation in the mare. *The best indication of mild endometritis in all species consists of accumulations of plasma cells and foci of lymphocytes in the stroma.* Resolution of this type of endometritis may occur with no more residue than a few cystic glands with periglandular fibrosis (Fig. 4.62), although during its course it may be responsible for a series of aborted embryos. If the endometritis is more severe or persists for a longer time, the cumulative damage to the endometrium may render the mare sterile.

Contagious equine metritis is a *venereal disease of mares* caused by ***Taylorella equigenitalis***, a gram-negative, microaerophilic coccobacillus. The disease produced by this organism does not appear to be significantly different from other common infecting organisms of the mare's genitalia. The interest in this disease stems from its apparently abrupt appearance in horse-breeding establishments in England in 1977 and its rapid spread to equine studs around the world. Strict control measures seem to have limited its spread and the clinical disease is now rare.

The disease causes temporary infertility in mares and a mucopurulent discharge that lasts 2–3 weeks. The organism can persist in infected mares for several months, and recovered mares represent an important reservoir of infection. Stallions transmit the organism by genital contact but do not develop clinical disease.

The temporary infertility that is the clinical hallmark of the disease is the result of mild to moderate inflammation of the endometrium and adjacent structures. After experimental introduction of the organism into the uterus, and presumably after natural infection, the bacteria can be regularly demonstrated in the uterine tubes, endometrium, cervix, and vagina for a 2–3-week period, during which time the organism elicits a mild to moderate inflammatory response. The endometrial folds are turgid and swollen and covered by a small amount of cloudy viscid exudate. At this stage the endometrium is edematous and the inflammatory infiltrate consists mainly of neutrophils. As the reaction subsides, the edema disappears and plasma cells predominate. Changes in the cervix parallel those of the endometrium. Salpingitis develops in some cases but is a less regular feature of the infection. Infection produces no gross changes in the vagina or vaginal vestibule, and histologic changes are mild. No lesions develop in the clitoral fossa or sinus, but the organism can be recovered from these sites after it has disappeared elsewhere.

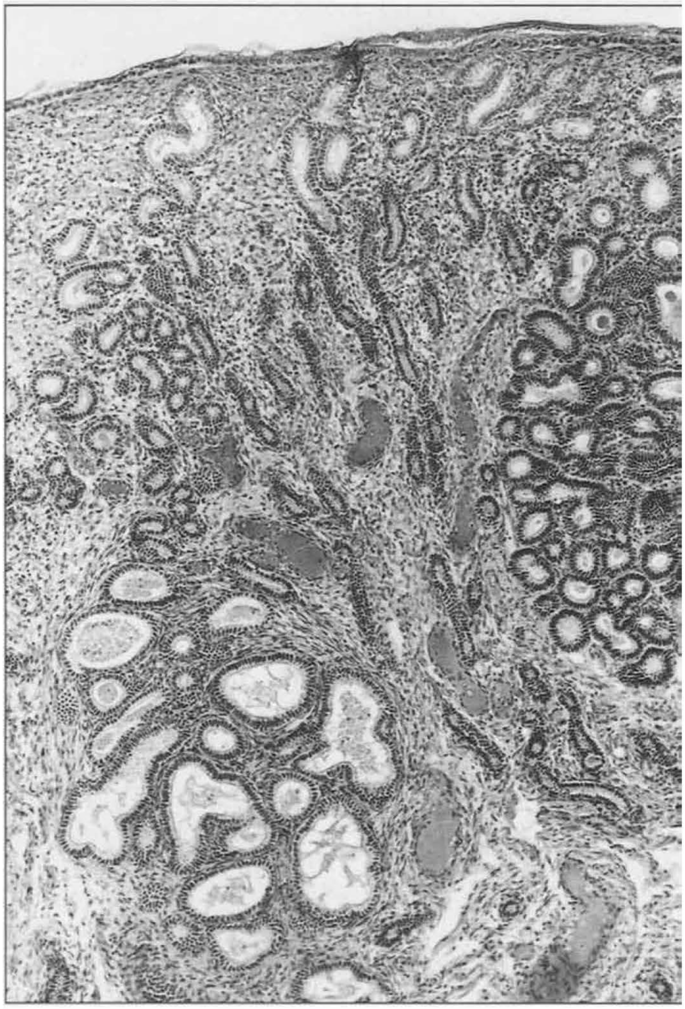

Figure 4.62 Endometrial tissue from a mare showing **glandular nesting**. Endometrial biopsy is routinely done in mares, tissues are evaluated, and a category (score) is assigned based on the presence and severity of endometrial fibrosis, inflammation, lymphatic dilation, and loss of glands. The clinical history is also considered. The most common system used, the Kenney–Doig, uses four categories (I, IIa, IIb, and III).

More severe grades of endometritis are common to the puerperium in **cattle**. Nothing of significance may be visible on the serosal surface, but the organ is enlarged and flabby, and collapsed rather than firm and contracted. The lumen contains chocolate-colored lochia that is slightly tenacious and often without foul odor. With the admixture of inflammatory exudate and placental detritus, the uterine content becomes progressively dirty gray-yellow. The endometrium is congested and swollen, and the intercotyledonary areas are ragged and tattered with shreds of mucosa free in the lumen. Small hemorrhages are common in the congested mucosa, and there is a prominent leukocytic infiltration massing at the surface involving all mucosal elements, including the glands. Where suppuration and superficial necrosis produce the tattered mucosa, the surface is comparable to a pyogenic membrane. The remainder of the genital canal may show nothing more than the traumatic lesions incident to parturition. If the uterus is paretic, there may be no discharge in the vagina.

Sporadic outbreaks of suppurative endometritis associated with *Bovine herpesvirus 4* have been reported. The histopathology is typical for herpesvirus infections, with focal necrosis, ulceration, and common secondary bacterial infections. Intranuclear viral inclusion bodies are found in endometrial epithelial and endothelial cells.

Metritis

The distinction drawn here between endometritis and metritis for purposes of description is that, *in metritis, all layers of the uterine wall show evidence of acute inflammation.* The uterus is paretic and there may be little or no vaginal discharge. The wall of the uterus is thickened with suffused blood and edema fluid and is very friable. The serosa is dull and finely granular with "paintbrush" hemorrhages and a thin deposition of fibrin, or the subserosal vessels may be darkly congested. Other than traumatic rupture, perforation with secondary peritonitis is not common except in anaerobic infections; death in untreated cases usually occurs first from toxemia or septicemia.

The secretion may be scant or abundant, is fetid, and is dirty yellow to red-black. The microscopic picture is that of purulent inflammation. Subserosal connective tissues are edematous and infiltrated with leukocytes, and the same process surrounds the blood vessels of the myometrium and permeates bundles of, and individual, muscle fibers, which themselves undergo granular degeneration. In metritis, as in acute endometritis, leukocytes mass on the mucosal surface and are associated with extensive hemorrhage, necrosis, and sloughing. Invasion of blood vessels, both arteriolar and venous, aggravates the lesion. Thrombosis may extend to the vessels of mesometrium with the usual sequelae of hemorrhage and infarction.

Chronic endometritis

Recovery from the acute phase of the infection often results in chronic endometrial involvement. With greater-or-lesser degrees of endometrial destruction and replacement by granulation scar tissue, the uterus takes on the nature of a fistulous tract. The changes depend on the duration and severity of the inflammation, but *consist essentially of productive fibrosis and leukocytosis in which lymphocytes and plasma cells predominate.* Thickening of the endometrium is by inflammatory tissue; the glands are depleted; those that survive are atrophic, flattened, and attenuated, or cystic due to periglandular fibrosis. The lining mucosa may be intact, denuded in places, or show foci of polypoid hyperplasia or squamous metaplasia, as do any chronically irritated mucous membranes. The exudate in the lumen is not copious and may be serous, catarrhal, or frankly purulent. Much of the labile endometrial stroma, especially that of caruncles, may be replaced by useless scar tissue, and dystrophic mineralization of necrotic portions of the endometrium may sometimes be extensive enough that the lining of the uterus feels gravelly.

It is estimated that 20% of cows with generalized **tuberculosis** and 4% of all tuberculous cows have involvement of the endometrium. There are three routes of infection, namely, hematogenous, via the uterine (fallopian) tubes from the peritoneum, and coital; of these, the last is exceptional. As in tuberculous lesions generally in cattle, *there are two anatomical forms of the lesion, miliary tuberculosis and diffuse caseating tuberculosis,* although transitional forms do exist. It is generally accepted that the disseminated miliary lesion is of hematogenous origin during the phase of early dissemination.

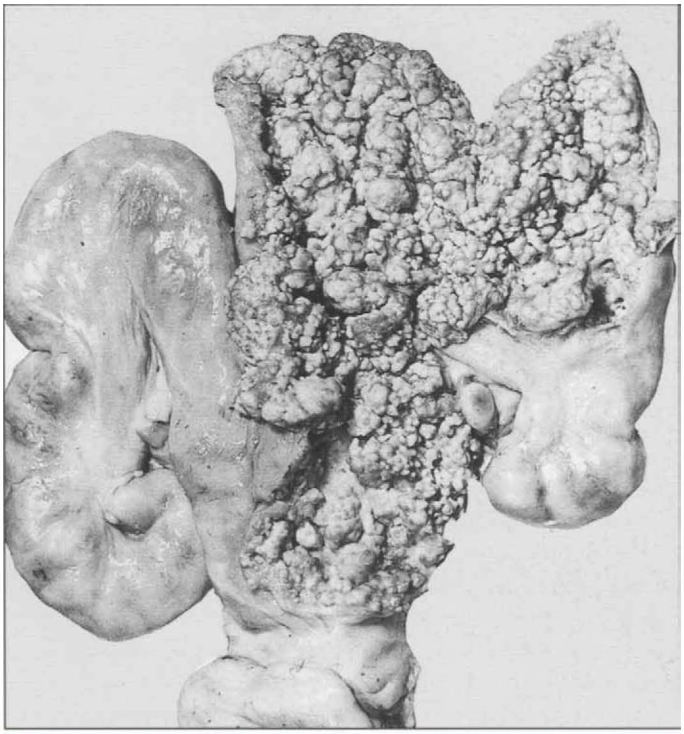

Figure 4.63 Granulomatous metritis in bovine tuberculosis.

In *miliary tuberculosis,* the uterus may appear normal externally. In the early stages, there may be no exudate in the lumen, but later, as the granulomas enlarge and ulcerate, the uterus will contain yellow purulent exudate. The granulomas are visible as few or many nodules in the mucosa, usually the more superficial portions, and microscopically are of typical tuberculoid structure. A common site is near the bifurcation of the uterus or in the caruncles of the pregnant uterus.

Caseous tuberculosis causes thickening and rigidity of the horns with serofibrinous or purulent fluid in the lumen. The endometrium is thickened, dry, and extensively caseous (Fig. 4.63). There may be intense leukocytic infiltration and marked exudation. The caseated area is usually demarcated by a zone of epithelioid cells from a margin of connective tissue.

In association with the uterine lesion in tuberculosis, there is often involvement of other portions of the genital tract. There may be multiple red granulations on the surface of the ovary and its ligaments (Fig. 4.64), or there may be enlargement of the ovaries with parenchymal tubercles. Tuberculous salpingitis or pyosalpinx is probably the rule when the uterine tubes are the portal of uterine infection. Similar lesions may be found infrequently in the lower

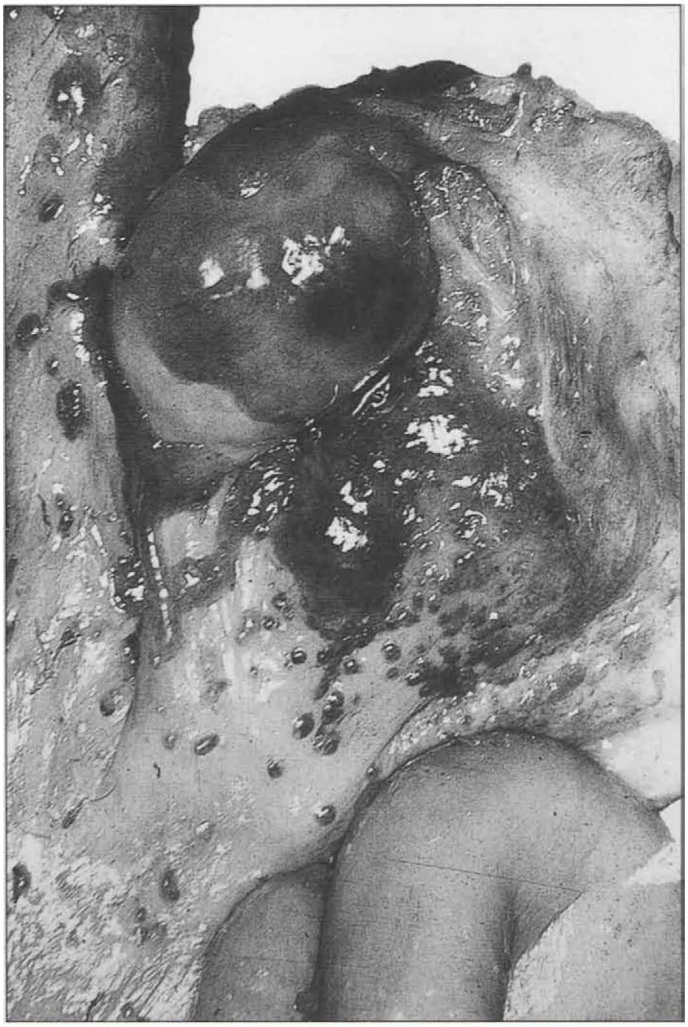

Figure 4.64 Serosal surface of mesovarium and ovary with granulomatous inflammation in **bovine tuberculosis**.

genital tract. Infection of cows with the avian strain of the organism also produces tuberculous metritis and placentitis with multiple small endometrial granulomas.

Uterine abscess

This is not a common observation. The localization of an infection to one part of the uterine wall is thought to follow severe metritis or localized traumatic injury to the infected endometrium. Such an abscess may reach 15 cm in diameter and is usually well encapsulated, although there may be some perimetrial adhesion and, in few instances, rupture into the peritoneal cavity or an adjacent hollow viscus.

Uterine abscesses are observed more frequently in cattle than in other species. There appears to be a relationship between the frequency of abscesses and uterine manipulations involving the use of instruments. *In cattle, most large abscesses are located in the dorsal wall of the uterine body.* This is the area most subject to trauma during the passage of insemination pipettes and uterine catheters. Abscesses that develop following severe metritis are usually small (1–3 cm) and do not have preferential sites.

Parametritis and perimetritis

Chronic adhesive peritonitis involving the genital tract does not usually result from septic metritis because the uterine serosa offers an efficient barrier to the spread of infection, and spontaneous rupture of an infected uterus is not common. Few virulent infections spread to the supporting ligaments. Excluding an origin from an extragenital focus, *perimetritis and parametritis in cattle usually follow manual manipulation of the ovary, pyosalpinx, obstetrical operation, removal of retained placenta, and uterine irrigations.* In each of the latter three circumstances, there may be accidental perforation or rupture of the uterus. The extent of the adhesion may vary from a few fibrous bands to dense connective tissue that obscures the contour of the organs and fixes them to adjacent viscera (Fig. 4.65). Abscesses may form in the adhesions of the ovarian bursa and the rectovaginal pouch.

Salpingitis

See the section on Pathology of the uterine (fallopian) tubes, above.

Pyometra

Pyometra is acute or chronic suppurative infection of the uterus with accumulation of pus in the uterine lumen. The escape of the pus is usually prevented by a functionally closed cervix. But the discharge may be prevented by an acquired or congenital cervical stenosis, and in mares the gravitational pull of the flaccid, distended uterus over the brim of the pelvis may limit the discharge of pus. Pyometra may occur as a sequel to uterine infections of the types described in the previous sections, but as it is a pathologic entity with a number of factors entering into its pathogenesis, it is considered separately here. Pyometra is an uncommon condition in the ewe and the sow. *It is relatively common in the bitch, queen, cow, and mare,* but the circumstances under which the disease develops in these species vary.

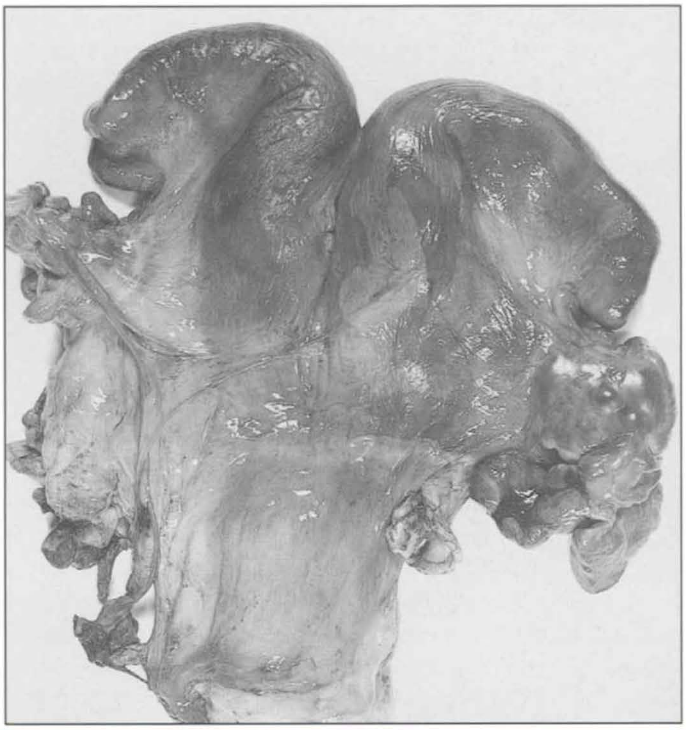

Figure 4.65 Pyometra with secondary adhesions in the uterus of a cow.

Pyometra in the bitch and queen

Pyometra in the **bitch** is a disease that characteristically affects older animals, especially those that are not bred. *The condition most often develops a few weeks after estrus.* Affected animals are depressed and anorexic, frequently vomit, and have polyuria and polydipsia, usually accompanied by a vaginal discharge. The pathologic findings vary with the stage of the disease. In less advanced cases, the uterus may be only slightly enlarged with mild endometrial hyperplasia and inflammation. In the more advanced stages, there is a remarkable distension of the uterine horns, which may come to occupy most of the peritoneal cavity (Figs 4.66, 4.67). (In contrast, pyometra in cattle most commonly develops in the postpartum period and is frequently associated with retention of fetal membranes (Fig. 4.68). If the purulent exudate does not drain from the uterus, it can become dehydrated with time and the inspissated material is found as soft concretions in the uterine lumen (Fig. 4.69).)

Distension of the cornua may be symmetrical or asymmetrical, uniform or ampulla-like dilatations, as in the uterus of mid-pregnancy. The cervix is completely or almost completely closed as a functional response to luteal hormones. The serosal surface of the uterus is dark and the vessels are congested and prominent. The wall is friable and either rupture or perforation with secondary peritonitis is not uncommon. There may be obvious inflammation of the peritoneal serosa and suspensory ligaments, but this is unusual. The nature of the uterine content is variable. In the more severe cases, usually those infected with *Escherichia coli* and *Proteus* spp., the exudate is thick, viscid, tenacious, opaque, red-brown, and with a characteristic fetid odor. In other cases, usually those infected with streptococci and staphylococci, the exudate is more typically purulent. The mucosa is irregular in thickness, necrotic, and ulcerated in portions with irregular superficial hemorrhages,

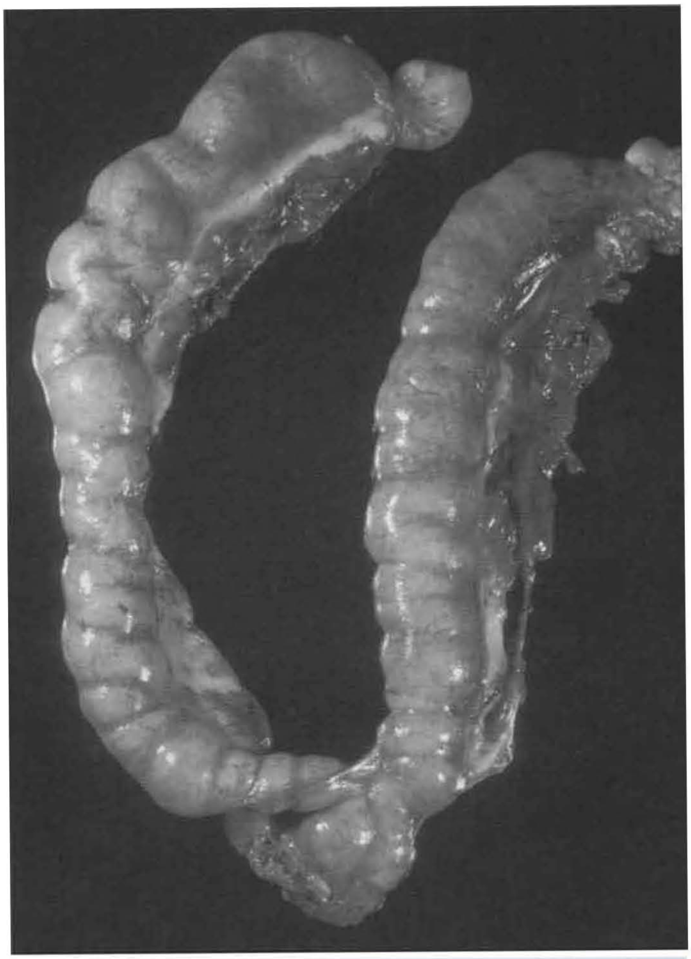

Figure 4.66 Pyometra in a bitch. Note the spiraling of the uterine horns, a change that occurs when the canine uterus is under the influence of progesterone. Both horns are mildly distended by purulent exudate. Cystic endometrial hyperplasia is commonly present (see Fig. 4.71).

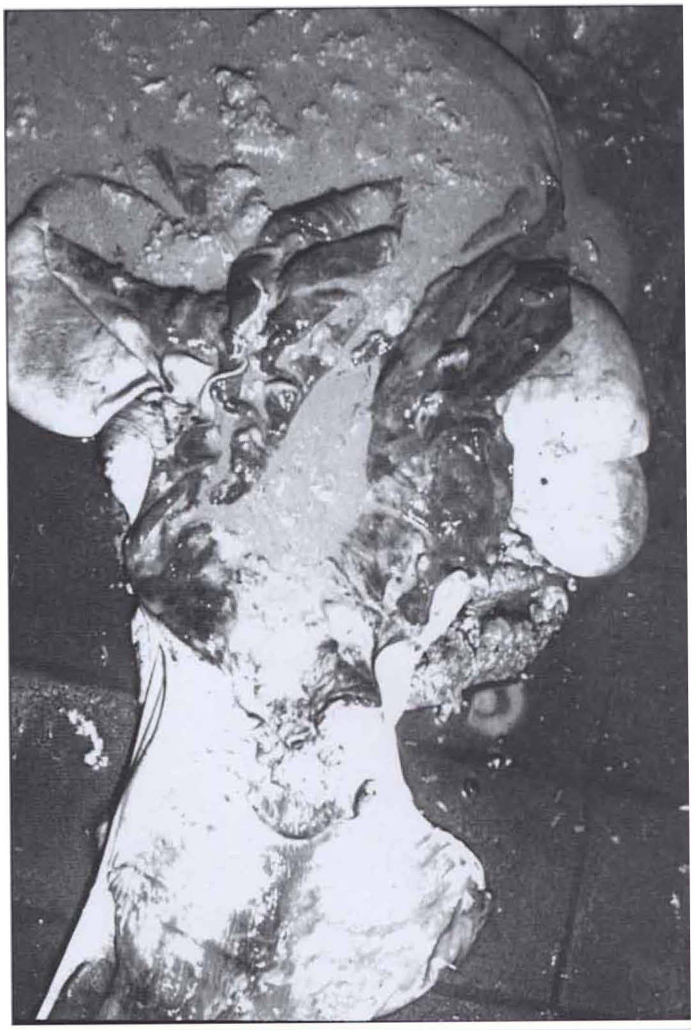

Figure 4.68 Pyometra in a cow.

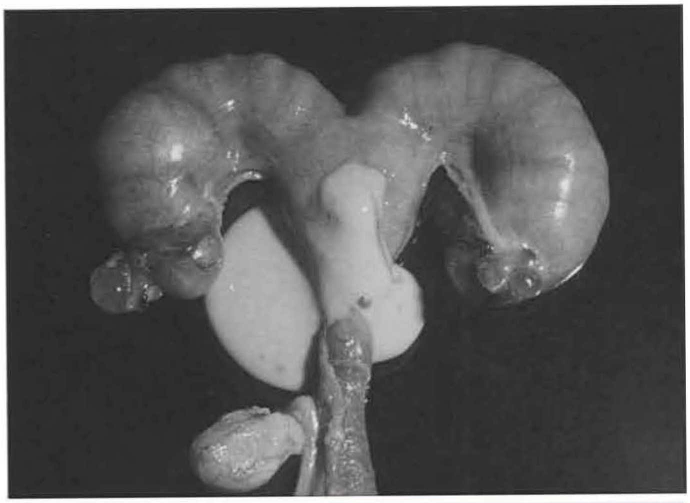

Figure 4.67 Pyometra in a queen.

and in other portions obviously hyperplastic, dull-white, and dry in appearance with small cysts visible in these hyperplastic areas.

Microscopically, the most significant feature is the remarkable endometrial hyperplasia and progestational proliferation in almost all cases (Figs 4.70, 4.71). The cells of such progestational epithelium are enlarged, columnar, vacuolated, and have small pyknotic nuclei. In some cases, the normal single layer of cells piles up to produce pseudostratification or localized papillary proliferations. Whatever remains of the endometrial lining may show this development, or it may be patchy and alternating with normal epithelium.

These changes are produced by the luteal hormones that inevitably pave the way for the development of this disease. *The histological changes due to infection vary with the bacterial cause and time.* Masses of neutrophils collect in the uterine lumen and in the glands, although there is relative sparing of the glands unless they are cystic. The migrating leukocytes collect near the surface and then penetrate the epithelium. In milder cases, there may be few neutrophils in the endometrial stroma, but they are not many when compared with the numerous plasma cells and lymphocytes. There may not be much vascular reaction over and above that of hormonal origin, although perivascular reaction and leukocytosis of lymphatic vessels are almost constant in the myometrium. Sometimes the reaction is much more severe than that just described, and in the endometrial stroma there are all the exudative phenomena of acute inflammation accompanied by the early reparative response of granulation tissue. The blood vessels are very congested and some show thrombosis, and about others there is diapedesis or larger hemorrhage.

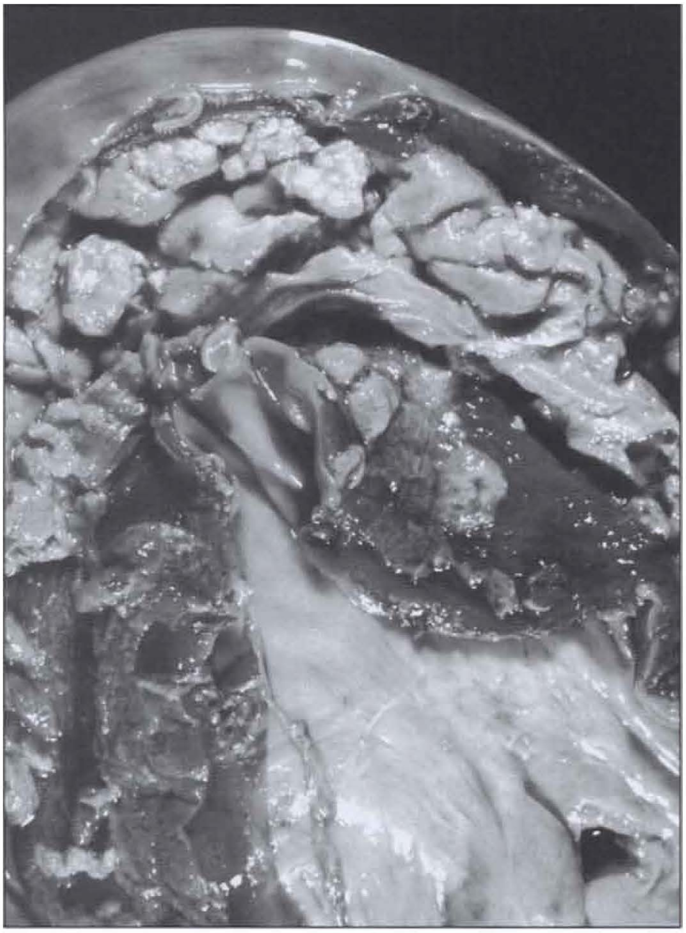

Figure 4.69 Chronic pyometra in a cow. Note the inspissated purulent exudate.

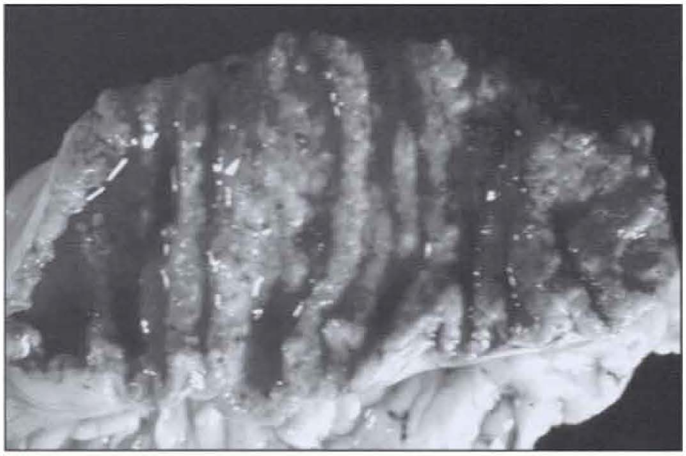

Figure 4.70 Cystic endometrial hyperplasia in a bitch. This uterine horn is opened, exposing the endometrial surface. The endometrium is thickened and there is uniform cystic distension of endometrial gland lumens. The bitch had purulent exudate in the lumen (pyometra).

The stroma is edematous and bullae often lift off the overlying epithelium. Numerous neutrophils infiltrate the stroma and collect in the lumen. There is little formation of fibrin, and rarely are there microabscesses in the mucosa.

It is clear that most cases of pyometra in the bitch are associated with endometrial hyperplasia. It is usually a disease of the diestral (metestrus) period, a time at which corpora lutea are present and progesterone levels are high and, since the condition has been produced both experimentally and accidentally by the administration of progestins, it is clear that *progesterone is an essential feature in the pathogenesis.*

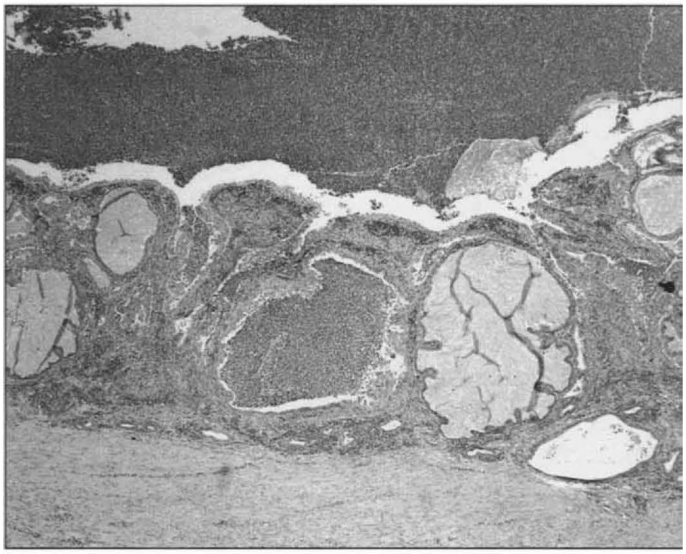

Figure 4.71 Canine pyometra with cystic endometrial hyperplasia (subgross photograph). During the luteal phase of the cycle, the canine endometrium is very sensitive to stimuli, responding by undergoing glandular and luminal epithelial hyperplasia with accumulation of secretions. This is followed by lymphocytic inflammation that becomes purulent when secondary bacteria invade the uterus.

Since cystic endometrial hyperplasia had been produced in dogs by administration of high levels of progesterone for extended periods of time, and since cystic endometrial hyperplasia was a hallmark of canine pyometra, it was presumed that cystic endometrial hyperplasia induced by abnormal progesterone secretion, or response, preceded and paved the way for the bacterial component. Some doubts concerning the validity of this view were generated when hormonal abnormalities could not be demonstrated in cases of pyometra. Now it has been shown that cystic endometrial hyperplasia can be produced in the normal, early-diestral uterus by mild trauma to the endometrium. The investigators scratched the endometrium with a thin wire, but endometrial biopsy has caused the same lesion. More directly to the point, inoculation of appropriate strains of *E. coli* into the uterine lumen, if given 1–2 weeks after estrus, causes a pyometra that has all the features of the natural disease, including cystic endometrial hyperplasia.

It appears that an appropriate stimulus applied to the progesterone-primed endometrium produces cystic endometrial hyperplasia and that one such stimulus can be a bacterial infection. Accordingly, rather than pyometra in the bitch occurring as the result of bacterial infection being superimposed on an abnormal endometrium, *it appears that the bacterial infection of the progesterone-primed endometrium produces both the pyometra and the cystic endometrial hyperplasia.*

The bacterium most commonly present in pyometra in the bitch is *E. coli*, and uterine *E. coli* isolates are typically identical or very similar to isolates from feces of the same bitch. Most of the strains involved are urinary tract pathogens and possess *uropathogenic virulence factors*, including P fimbriae, α-haemolysin, and cytotoxic necrotizing factor 1, that probably enhance the pathogenicity of the strain in the canine genital tract and may facilitate the colonization of the progesterone-primed endometrium. Urinary tract infections are common in bitches with pyometra, and the strains of bacteria infecting both are often identical. It seems probable that the urinary infection predisposes to pyometra, and that the uterus is infected at the stage that suitable receptors are developed in the endometrium in response to hormone stimulation. This explanation of the bacterial infection can be only a partial one as not all bitches with pyometra have urinary tract infection, and not all infecting organisms are urinary pathogens. In some cases of pyometra, bacteria cannot be recovered.

The clinical signs and extragenital lesions associated with pyometra in the bitch are due to severe intoxication and probably also intermittent bacteremia. Renal signs and lesions are common. Profound hypotension may reduce renal perfusion and lead to prerenal uremia. This is worsened by membranoproliferative glomerulonephritis that often develops as a result of immune-complex deposition. Polyuria, which is such a common feature of the disease, is due to impaired tubular ability to concentrate urine. The mechanisms involved in this are not completely understood, but they are thought to be brought about by *E. coli* antigen and have an immunologic basis. Most animals have profound leukocytosis, reflected in the bone marrow as an increased myeloid-to-erythroid ratio. There is myeloid hyperplasia in bone marrow and extramedullary myelopoiesis in liver, spleen, lymph nodes, and adrenals.

Pyometra in the **queen** is roughly comparable to the disease in the bitch, but there are differences, some of which are related to the differences in the estrous cycle of the two species. Cats are induced ovulators, and usually if not bred have repeated estrous periods. However, *pyometra develops most often 2–5 weeks after estrus*, and usually after spontaneous ovulation and presumably corpora lutea formation. Unlike the bitch, many queens with pyometra do not have corpora lutea present in their ovaries at death or surgery, but approximately half do, and *there is an obvious correlation between the presence of corpora lutea and the development of pyometra in queens.* The correlation with endometrial hyperplasia is less clear. Most queens with pyometra do have some degree of cystic endometrial hyperplasia, but this change is very common in the age group affected.

Pyometra in the cow

Pyometra in the cow is also associated with corpus luteum activity in the ovary. However, in contrast to the situation in the bitch in which the high progesterone levels of early diestrum predisposes to uterine infection, *in the cow, uterine disease causes the corpus luteum to persist and maintain a high progesterone level.* The retention of the corpus luteum appears to be due to a reduction in or inhibition of the synthesis and release of the luteolytic factor, prostaglandin-$F_{2\alpha}$, by the diseased endometrium.

Broadly, there are two periods in which a uterine infection can lead to retention of a corpus luteum with the accompanying hormonal effects that *convert an endometritis to a pyometra.* They are during the *early postpartum period*, following dystocia, retained placenta, and metritis, and at *various times after breeding*, as a result of venereal infections with early embryonic death. Insemination during the luteal phase of the cycle or similar operations that can introduce contamination into the uterus during the luteal phase can mimic venereal infection.

The role of retained luteal tissue in the pathogenesis of pyometra appears clear. The secreted progesterone endows the uterus with a high degree of susceptibility to infection, maintains functional closure of the cervix, and inhibits myometrial contractility.

The amount of pus retained in the uterus of a cow with pyometra varies from a few milliliters to more than several liters and is thick, rather mucinous, and cream or gray-green colored. The cervix has no seal of mucus so, although contracted, there is usually escape of a small amount of pus into the anterior vagina. The wall of the uterus is thick, doughy, and paretic but, in long-standing cases, especially as complications of mucometra, the walls are thin or fibrosed. The histological changes do not differ significantly from those of endometritis of comparable duration and severity. The organisms involved are hemolytic streptococci, staphylococci, coliforms, *Arcanobacterium pyogenes*, and *Pseudomonas*. The venereally transmitted protozoan, *Tritrichomonas foetus*, can be the cause of pyometra after breeding.

Rarely, the anomalous developments of the uterus that were described earlier can lead to pyometra. In the segmental aplasias and with imperforate hymen, the lumen proximal to the site of obstruction becomes distended with mucus and cellular detritus. These closed cavities provide a satisfactory environment for bacterial growth, but this is not a frequent complication. When it does occur, the source of infecting organisms is probably hematogenous. Pyometras seldom spontaneously resolve and, although the condition is not usually life-threatening as it is in bitches, unless cyclic activity can be reinstituted, the condition will persist.

Pyometra in the mare

Pyometra in the mare differs from the disease in the bitch and the cow in several particulars. While some cases develop following difficult parturitions with infections, as they do in cattle, many do not. Remarkably, most mares continue to cycle during the disease, and the hormonal influences that are so marked in the bitch, queen, and cow are much less important in the mare.

In some mares, cervical adhesions and closure may lead to pyometra, but in most instances the purulent material collects without demonstrable cervical closure, and in some cases the cervix is fully dilated. Copious amounts of pus can be discharged under such circumstances, particularly during estrus. *Pyometra in the mare seldom leads to evidence of systemic disease*, although some mares develop mild anemia.

The length of the estrous cycle appears to be related to the severity of the endometrial damage. In rare cases, where the endometrial damage is severe, the cycles are prolonged with long luteal phases due to delayed or inadequate prostaglandin $F_{2\alpha}$ release. Mares with less severe endometritis have normal or shortened cycles.

A variety of organisms may be present in pyometra in the mare: *Streptococcus zooepidemicus* is the most common, but *E. coli*, *Actinomyces* spp., *Pasteurella* spp., and *Pseudomonas* are often present.

Endometrial biopsy

Endometrial biopsy is most firmly established in *equine theriogenology*. The evaluation system is based on identification and scoring of four microscopic lesions plus consideration of the mare's reproductive history. *The microscopic features evaluated include inflammation, dilation of lymphatics, loss of glands, and presence of fibrosis.*

Only a small amount of information has been published on endometrial biopsy in other species. Pathologists are asked to evaluate endometrial biopsies for cattle and from bitches, and as more information is gathered and evaluated, recommendations for scoring will be followed by validation of their prognostic value.

Pathology of the gravid uterus, placenta, and fetus

General considerations

It is difficult to generalize on the subject because of the remarkable variation in the reproductive affairs of the various species. Because the mechanisms by which the gestation period is initiated, the pregnancy maintained, and the delivery triggered have such profound effects on how diseases of the conceptus will be manifest, some review of the special features of reproductive patterns in the various domestic species is given here.

For a pregnancy to proceed, cattle, sheep, goats, swine, and horses require that the normal cyclic lysis of the corpus luteum be prevented. This is achieved in **cattle** by secretion by the blastocyst of interferon-γ, which inhibits synthesis and release of prostaglandin $F_{2\alpha}$ from the endometrium. This spares the corpus luteum and allows it to serve as the corpus luteum of pregnancy, and it then provides part, or all, of the hormonal support of the pregnancy. In cattle, up to 40% of total embryonic loss probably occurs between days 8 and 17 of pregnancy. Early embryonic death will permit release of prostaglandin $F_{2\alpha}$ and lysis of the corpus luteum and subsequent reinstitution of the estral cycles in these species. The delay between death of the conceptus and the return of the dam to estrus is usually sufficient to allow for complete or near-complete autolysis and dissolution of the fragile embryo. As a result, *the early diseased products of conception are rarely available for study.* Venereal infections cause some of the early losses, but on the basis of the few studies that have been done, and on the experience in other species, *it is presumed that chromosomal abnormalities account for most of these early losses.* In monotocous species, embryos that die undergo prompt dissolution, the products are expelled, and the disease is recognized only as infertility with slightly prolonged estral cycles. The death of a single embryo, or even several, does not interrupt the pregnancy in swine and dead embryos are resorbed or mummified. Rarely, the death of the conceptus may be caused by organisms that convert the pregnancy to a pyometra, the active infection preventing the lysis of the corpus luteum. Trichomoniasis of cattle is an example of a venereal infection that can lead to pyometra.

In the **mare**, gonadotropic hormone (equine chorionic gonadotropin) is produced in ulcer-like structures in the endometrium, *the endometrial cups* (Fig. 4.72). These structures form early in pregnancy and were originally thought to be maternal in origin and part of the mare's adaptation to pregnancy, but it has been shown that the cells that make up the cups are fetal in origin and develop from a band of elongated trophoblast cells of the chorionic girdle. These cells become detached from the fetal chorion on about day 35 of gestation and burrow into the stroma of the endometrium. There the cells enlarge and take on the appearance of decidual cells.

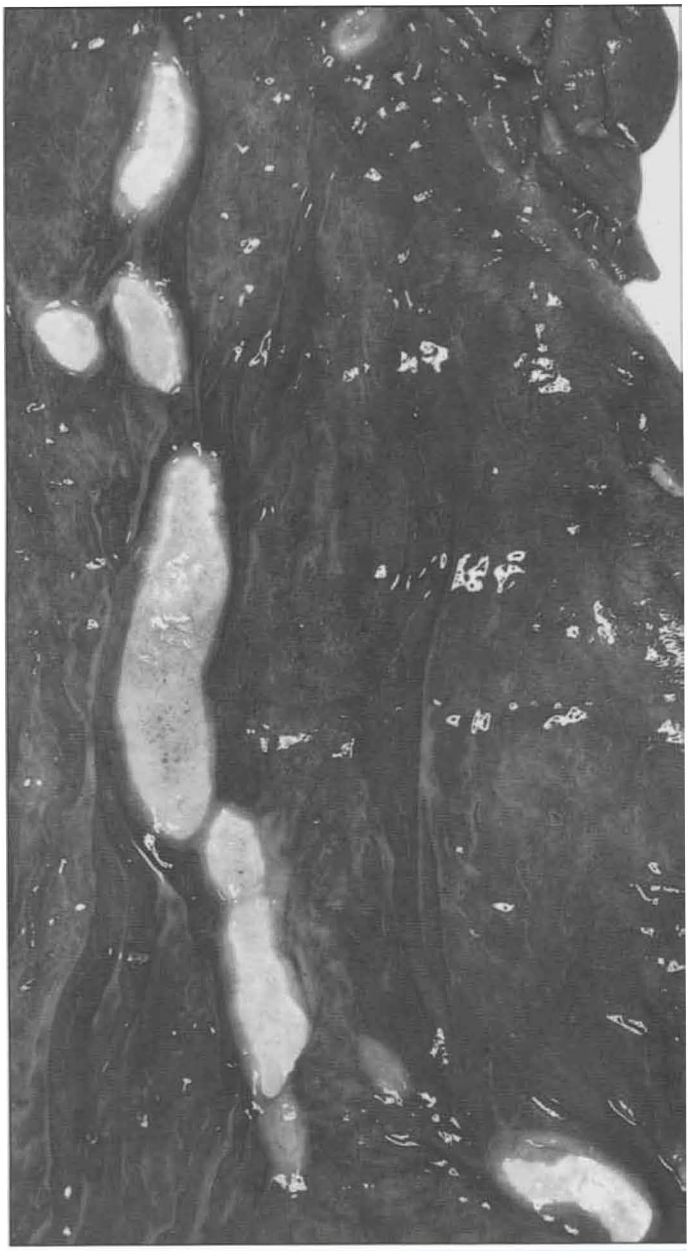

Figure 4.72 Endometrial cups in the uterus of a mare; these are the sites of production of gonadotropic hormones.

The cup tissue becomes visible at about day 40 of gestation as a horseshoe or ring-shaped band in the endometrium of the pregnant horn. The cups increase in size until day 60 of gestation, at which time their hormone production is at a maximum. Hormone levels fall after day 60, and the cups become pale and slough between days 75 and 100 of gestation. The degeneration of the cups resembles graft rejection. The cells of the fetal chorion are surrounded by maternal lymphocytes and undergo prompt degeneration. The necrotic slough is detached and lies free between the endometrium and allantochorion.

This potent chorionic gonadotropin in mares stimulates ovarian corpora lutea to develop, and these maintain the pregnancy until approximately 126–140 days, when the fetal chorion takes over the production of progesterone. If the conceptus dies after day 35 of gestation, at which time the fetal cells have invaded the endometrium, the cups form and secrete chorionic gonadotropin, accessory corpora lutea are produced, and the mare fails to return to estrus and continues for a variable period in a state of pseudopregnancy.

Domestic carnivores do not have estral cycles that require interruption in order to begin a pregnancy. Once formed, the corpora lutea usually persist during most of the gestation period. They develop after ovulation, spontaneously in the case of the bitch and induced by coitus in the cat. Once formed, their lifespan appears to be inherent and the hormone production by them to be independent of a pregnancy until the last stages of gestation. As a result, death of the embryos, or death or sickness of the fetuses, shortens the length of the gestation period only slightly. Fetal death before the terminal stage does not usually lead to premature delivery; rather, the process of autolysis and resorption or mummification begins, and the products are expelled at or near term. *As a consequence, it is very rare to obtain diseased fetuses from these species in a satisfactory state for study.* Most studies of fetal diseases in carnivores have been based on experimental investigation.

The corpus luteum is essential for the maintenance of pregnancy during the entire gestation period in swine and goats, as it is in dogs and cats, before term. The corpus luteum is only essential during the first half of pregnancy in the cow, mare, and ewe. During this time, the effects of fetal death are unpredictable. In some cases the corpus luteum may undergo luteolysis and the dead fetus or fetuses are expelled, usually severely autolysed, but in some cases the corpus luteum will not be lysed and will persist, and the fetus will be resorbed or more likely expelled. If the fetus is older, and particularly in cattle, it may be mummified. During the last third of gestation in these species, the pregnancy requires hormonal support from the fetus, and fetal death at this stage leads to expulsion within a few days. Even a few days allow time for autolysis to be evident; the fetal tissues are pale, the red cells lysed, and pleural and peritoneal cavities are filled with hemoglobin-stained fluid.

The **mechanisms of parturition** are similar in most mammalian species. Labor requires the coordinated contractions of the smooth muscles of the uterus. These are supplemented during the expulsive phase of labor by contraction of the abdominal muscles. Preceding the muscular phase, there must be changes in the connective tissues in the cervix, uterus, and vagina, allowing these tissues to become compliant.

The *timing of parturition* is species-specific and related to appropriate fetal maturity. How the fetal maturity is sensed and how it is translated into maternal myometrial contraction appears to vary between species and is unknown for most. Knowledge of fetal control of parturition has been gained largely in sheep, a species in which fetal control of parturition is nearly absolute. In other species, the fetus plays a lesser role or none at all.

Parturition in the **ewe** is initiated by a sharp rise in cortisol secretion by the adrenal cortex of the fetal lamb. The increased secretion is partly due to increased responsiveness to corticotropin and partly to increased fetal adrenocorticotropic hormone production. It has been shown experimentally that either hypothalamic or pituitary destruction or bilateral adrenalectomy in the lamb fetus will prevent its initiation of parturition and indefinitely prolong gestation. Fetal cortisol induces enzyme synthesis in the placenta. These enzymes synthesize estrogen from progesterone, increasing placental estrogen production and decreasing progesterone. The change in ratio of estrogen to progesterone stimulates release of prostaglandin $PGF_{2\alpha}$ from the maternal endometrium. $PGF_{2\alpha}$ induces compliance in the cervix by changing the physical properties of the collagen fibers. These alterations are based in part on loss of collagen but more to an increase in glycosaminoglycans and water that loosen the matrix in which the collagen fibers are imbedded. The $PGF_{2\alpha}$ also enhances the myometrial response to oxytocin and stimulates uterine contractions. The mechanism by which parturition is triggered in cattle appears to be similar to those in sheep. Parturition in the corpus luteum-dependent species is initiated by regression of the corpus luteum and a corresponding fall in circulating progesterone. The details are only known in the goat, in which species the fetal adrenal cortex produces a cortisol surge that produces $PGF_{2\alpha}$ release and luteolysis. It is unlikely that the fetal control of parturition in other corpus luteum-dependent species is as strong as it is in goats.

The mechanisms by which dead fetuses are expelled in cattle and sheep are not known, but it is probable that they share features with normal parturition. They must involve $PGF_{2\alpha}$ release, cervical compliance, and coordinated myometrial contraction. Chronic fetal disease in cattle and sheep results in premature delivery of live but diseased fetuses. Since fetal stress activates the same hypothalamic–pituitary–adrenal endocrine chain used to initiate normal parturition, it is probable that chronic fetal disease operates through the same chain to cause abortions of live fetuses. Equine herpesviral infection regularly produces abortion of live, diseased, equine fetuses, but very little is known of the mechanisms involved in either these abortions or normal parturition in this species.

Embryonic death

There is little that can be said with profit of the pathology of the ovum, zygote, or early embryo, but a brief consideration is included here for purposes of orientation.

When fertilized ova die, they undergo progressive cytolysis within the zona pellucida, which often remains intact after the cytoplasm and nucleus are dead. The whole structure then disintegrates and is resorbed or discharged at the next estrus. It is rare to recover abnormal ova from the bovine uterine tube during the first 72 hours postestrus. Presumably, in those cases in which estrus occurs after a normal cycle, the ova die most commonly between days 4 and 10 of the cycle. Most embryonic deaths in cows, however, are associated with prolongation of the interestrual period. In the embryonic stage, the embryonic tissue proper disappears first and the trophoblast remains for a while before degenerating.

The incidence of zygotic and embryonic mortality is remarkably high in the species that have been studied, and probably is in all species. Humans and the domestic species studied suffer a zygotic loss of 15–30%. The causes are presumably diverse and may vary somewhat from species to species. However, the demonstration of abnormal karyotypes in early porcine zygotes and in a high percentage of unselected spontaneous human abortions *suggest that chromosomal abnormalities are an important cause of this mortality*. The frequency with which chromosomal abnormalities are found varies with the stage of pregnancy; they are most common in the early stages of pregnancy. This is the pattern one would anticipate since some of the most severe anomalies are not compatible with attachment or implantation. Most of these chromosomal abnormalities represent numerical changes such as monosomy, polysomy, polyploidy, and mixoploidy. Only a small percentage is structural. The monosomies and polysomies are the result of nondysjunction during meiosis or early cleavage stages. Triploidy can be caused either by two sperm fertilizing one egg, or by the suppression of the second polar body and one sperm fertilizing a diploid egg; both possibilities increase with increased age of the gametes. Tetraploidy occurs as a result of suppression of the first cleavage division of the zygote. Mixoploids develop as a consequence of mitotic error during cleavage division of the zygote. Structural anomalies are caused by spontaneous breakage and reunion. Viruses, drugs, and radiation are known to cause this type of chromosome damage.

Fetal death

A degenerate zygote or early embryo may be resorbed or expelled from the uterus. At a later stage in development, *the dead fetus may be mummified, macerated, or aborted; an* ***abortion*** *is defined as the expulsion of a fetus prior to the time of expected viability*. A dead fetus delivered within the period of expected viability is arbitrarily referred to as **stillborn**. It should be appreciated that these different terms might be applied to fetuses suffering from the same basic disease.

In uniparous domestic animals, death of the fetus in late pregnancy is usually followed by abortion. In multiparous species, if most of the fetuses die at the same time, all are likely to be aborted, but it is more usual for one or several dead fetuses to be retained with the remaining viable ones and delivered at parturition. It is often apparent that the deaths have occurred at different ages, the dead fetuses being of different sizes and degrees of mummification or maceration (Fig. 4.73).

Mummification of fetus

Mummification of a dead fetus is seen occasionally in any, but usually multiparous, species and most commonly in the sow. In the mare, it is typically one of twin fetuses that is mummified. Mummification may also occur in mares receiving progesterone in the early stages of gestation in order to prevent abortion associated with failure of endometrial cup development and subsequent failure of accessory corpora lutea formation and thereby progesterone production. The injected progesterone inhibits contractions of the uterus and, if the fetus dies, prevents abortion, so the fetus mummifies. *A prerequisite for mummification is that bacterial infection is not present*. The fluids are resorbed and the membranes become closely applied to the desiccated fetus. The whole mass becomes brown or black and rather leathery, moist on the surface with sticky mucus, but without odor or exudate. The time required for complete mummification will depend to some extent on the size of the fetus. Dehydration is advanced by 7 days in sheep fetuses; however complete mummification probably requires as long as 6–8 months in the case of a 6-month bovine fetus. All stages may be observed from the earliest of beginning separation of the placenta with hemoglobin staining of the tissues, to the latest, when all that remains is a firm and shrunken remnant consisting almost wholly of dried skin and bones. Until the time of expulsion, which on occasion occurs spontaneously, or parturition in multipara that still carry some viable fetuses, the cervix remains closed and sealed. In uniparous animals, the mummified fetus may be retained indefinitely. Animals that have had and delivered a mummified fetus usually breed normally on subsequent occasions so there cannot be any serious uterine lesion accompanying the fetal death. Genetic diseases (both inherited and chromosomal abnormalities), viral and protozoan

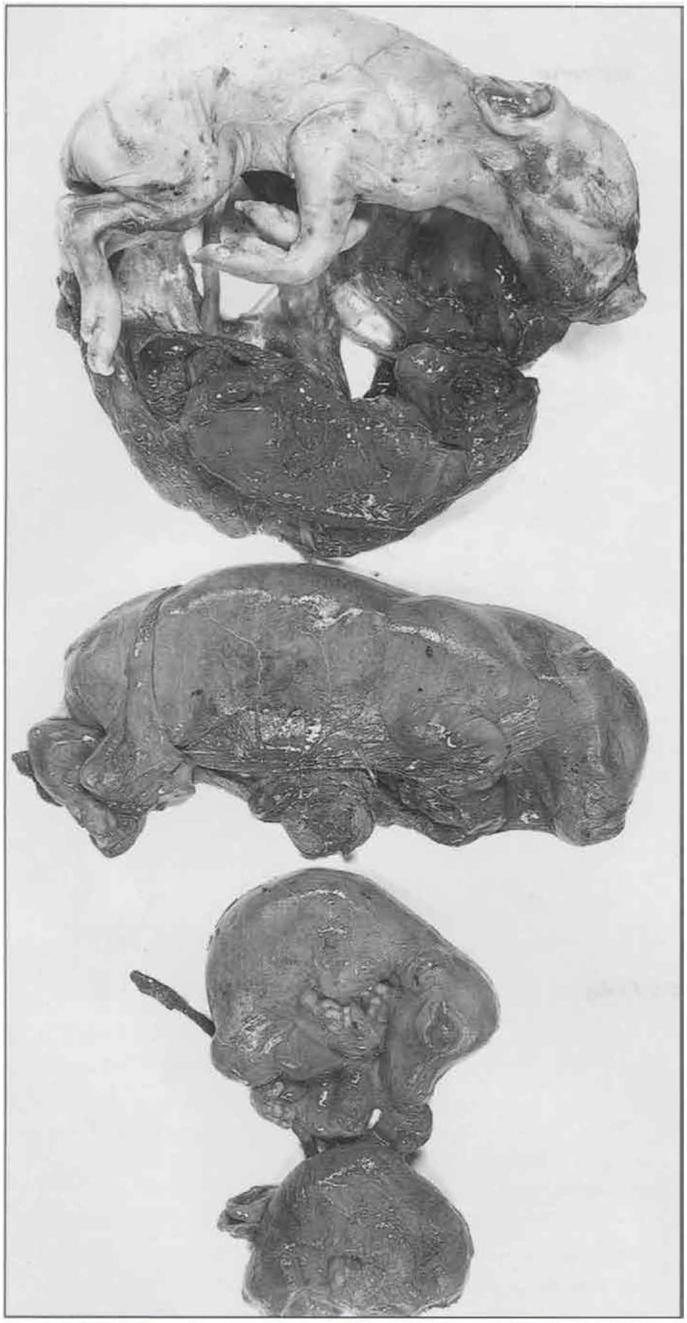

Figure 4.73 Porcine littermates that have died at differing stages of gestation and are undergoing **mummification**.

infections, and placental insufficiencies have been proposed as the causes of fetal death leading to mummification, but the cause is rarely firmly established in any particular case. Very likely all the proposed causes and others can produce fetal death at an appropriate time, and mummification can result. *The critical features for mummification appear to be the retention of the dead fetus within the uterus through the action of a functional corpus luteum, and fetal skin mature enough to resist autolysis.*

Fetal maceration and emphysema

Maceration and emphysema of the fetus require the presence of an infection in the uterus. If the early embryo succumbs to uterine or embryonic infection, maceration is usually followed by resorption from the uterus or expulsion along with a small amount of purulent exudate. This is the usual course of events in venereal infections by *Campylobacter fetus* and *Tritrichomonas foetus* in cows, but is also to be expected with any sort of nonspecific endometrial infection. The causes of infectious death of the conceptus during the period of the fetus are the same as above, but the consequences, pyometra or acute endometritis, are usually more severe because of the presence of decomposing fetal remnants. The differences between pyometra and endometritis are as discussed earlier; in pyometra, the corpus luteum may persist, the cervix remains sealed, and the uterus withholds its contents. If the corpus luteum and cervical seal break down, there is a purulent discharge of the contents, and except for the presence of fetal remnants, this endometritis does not differ much from that of the puerperium. After about the third month of pregnancy in the cow, complete fetal maceration does not occur. The bones, either more or less complete or only the ossification centers, resist maceration (Fig. 4.74). They may be discharged or retained in the pus of pyometra indefinitely, often near the cervix. The uterine pus is usually thick and intensely fetid, but this depends on the nature of the infection; in trichomoniasis, the exudate is watery and odorless.

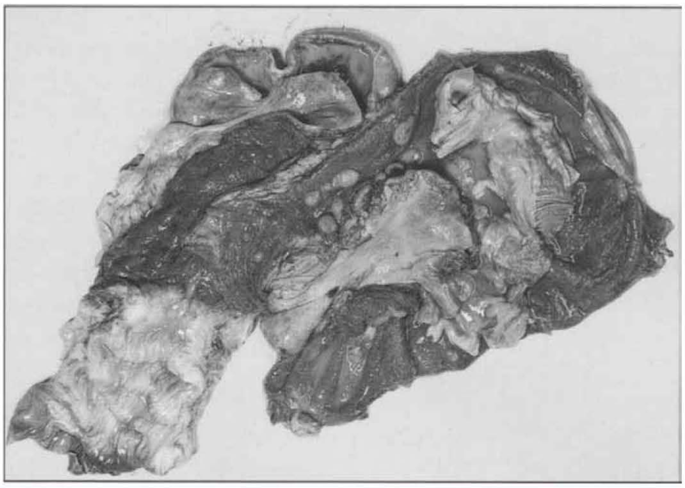

Figure 4.74 Macerating bovine fetus.

The usual infectious causes of fetal death and endometritis are not potent gas-formers; the development of fetal emphysema almost invariably depends on patency of the cervix and on invasion of the uterus and dead fetus by putrefactive organisms from the vagina. There are two common antecedents to emphysema: dystocia at or near term, and incomplete abortion. In incomplete abortion, the cervix is open but not completely dilated and the fetus may be delivered into the cervix or anterior vagina or, because of malpresentation, uterine inertia, or inadequate dilation of the cervix, it may be retained in the uterus. The fetus putrefies, becomes distended with foul gas and crepitates. If the fetus is small, the dam may survive the initial acute episode of fetal emphysema, after which maceration occurs in a chronic, foul purulent metritis. The cervix is not sealed, but because of uterine paresis, the pus is retained in the flaccid, dependent organ.

Advanced uterine lesions accompany the macerated fetus. The uterine wall is thickened and the reaction within it varies from the acute exudative inflammation of pyometra to more or less complete sclerosis and replacement by granulation tissue in long-standing cases. In these, the uterus closes firmly about the bones, and the bones may cause perforation.

Fetal emphysema, at or near term, complicating dystocia is fatal unless treated, and maceration is not an expected sequel. In some cases of uterine torsion, however, the twisted cervix and vagina produce an adequate seal against bacterial invasion of the dead fetus, and mummification, rather than maceration or emphysema, results.

A special form of fetal emphysema occurs in ewes, caused by *Clostridium chauvoei*, the organism responsible for blackleg. It affects fetuses near full term, causing acute tympanitic distension of the uterus, typical hemorrhagic and necrotizing lesions of the fetus, and the accumulation of dark thin discharge in small amounts in the uterus. The pathogenesis of this special infection is not entirely clear, but there is usually a relation to rough handling such as at shearing.

Embryonic death with persistence of membranes (cystic placental mole)

This is an uncommon development that can follow embryonic death. In the period of the embryo, the fetal membranes are in volume and mass the greater part of the products of conception, and *it is possible for the embryo to die and to be resorbed while the membranes persist and continue to grow. The remaining empty cyst has been referred to as a* **cystic placental mole**. Most empty placental cysts correspond in size to fetal membranes at 3–4 months of gestation. There is usually no patent lumen to the cyst. It is filled with a mass of clear-gelled fluid together with placental stroma. In those cases with placentary development, the allantoic and amniotic epithelia may be present. The condition may become infected and converted to a pyometra, or undergo necrosis and be discharged. Infections that result in rapid death of the fetus (e.g., bovine herpesvirus, *Arcanobacterium pyogenes*, *Histophilus somni*) usually result in a severely autolysed fetus, as time is required for the corpus luteum to lyse, the cervix to dilate, and for prostaglandin to contract the uterus and expel the fetus. In infections that are chronic and take time to kill the fetus (e.g., *B. abortus*, most mycotic abortions, *Yersinia pseudotuberculosis*), the preparations for abortion may be complete by the time the fetus dies and therefore the fetus will be aborted in a relatively well-preserved condition. In infections that are largely confined to the amnion, such as *Ureaplasma diversum*, the probable mechanism involves macrophage activation resulting in cytokine-induced production of prostaglandin by the endometrium, lysis of the corpus luteum, and premature delivery of a well-preserved or slightly autolysed fetus, depending on how quickly death follows the infection.

Adventitial placentation (semiplacenta diffusa)

The development of intercotyledonary placentation in cattle is a mechanism of compensation for inadequate development of placentomes. The inadequate number of placentomes is primarily endometrial, and may be congenital or acquired. There are normally 75–120 caruncles in the cow, and 40–125 in the ewe and goat. Not all of them are fully utilized in a normal single pregnancy. Occasionally, the numbers are much less as a congenital disorder of endometrial organization; more commonly, the reduction in number is acquired by inflammatory destruction of portions of the endometrium. Compensation consists of a great increase in the size of remaining caruncles during pregnancy, many of which may fuse, and by the development of a more primitive villus placentation between the placentomes (Figs 4.75, 4.76). *The adventitious placenta develops first adjacent to the placentomes*; the process may remain localized or involve virtually the entire intercotyledonary placenta, chiefly along the floor of the uterus. In the latter instances, pregnancy is insecure and may not proceed beyond mid-term. Hydrallantois is a complication. Adventitial placentation has not been observed in the sheep or goat placenta.

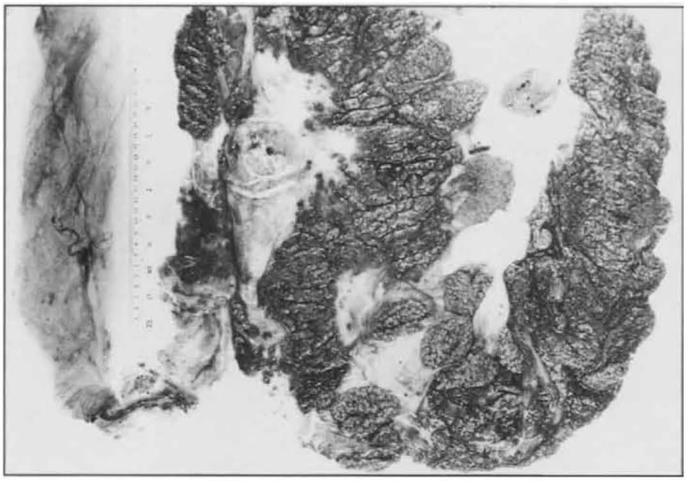

Figure 4.75 Adventitial placentation in the placenta of a cow.

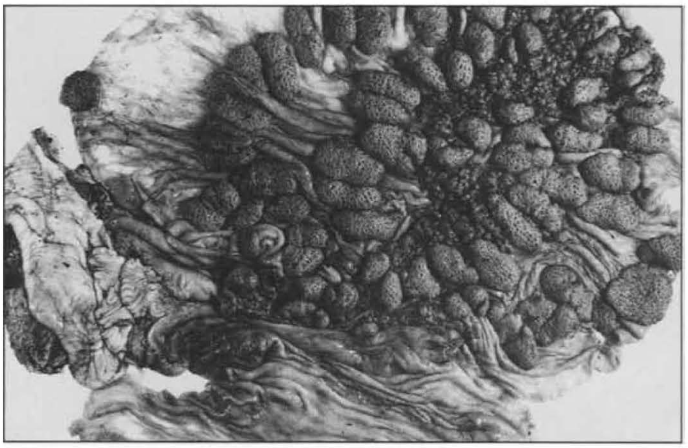

Figure 4.76 Uterus from a cow with **adventitial placentation**.

Hydramnios and hydrallantois

Excessive accumulations of fluid in the amniotic and allantoic sacs are infrequent diseases of pregnancy. They occur most often in cattle, and are rare in other species. Excess fluid may accumulate in both sacs, but this is the exception. The source, nature, and control of the fluid in the two sacs are different, and the conditions that give rise to excess fluid in each sac tend to be different. The total amount of fetal fluid increases progressively throughout pregnancy, and the volume at term in cattle is between 15 and 20 liters. This represents a fivefold increase during the last 4 months of gestation. The relative quantity of fluid in each sac varies during the gestation period. During the first and third trimesters, the amount of allantoic fluid is greater.

The nature of the fluid in each sac varies during gestation. At term, the amniotic fluid is glary, slightly viscous, and consists largely of fetal salivary secretion, the volume being largely controlled by fetal swallowing. The allantoic fluid is thin and watery and is derived from the fetal kidney via the urachus.

Hydramnios, or hydrops of the amnion, is usually associated with malformation of the fetus. The malformations may be either inherited or acquired. A variety of inherited diseases can cause hydramnios. There is a high incidence of the condition: in bison-cattle hybrids, in association with chondrodystrophic and muscle contracture malformations of bovine and ovine fetuses, as well as in other types of fetal malformation, particularly those involving gross facial anomalies.

Hydrallantois in cattle is most often associated with uterine disease with inadequate numbers of caruncles and the development of adventitial placentation. It also occurs with increased frequency in cows bearing twins. The quantity of excess allantoic fluid may be as much as 170 liters, but it is not notably different in quality from normal. The fetal membranes are only slightly thickened, but may be tough and rupture with difficulty. Dystocia with uterine paresis, retention of placenta, and metritis are sequelae of those few cases that do not abort earlier in gestation. The fetuses are usually dead when aborted or delivered at term and small for their age, but may have anasarca and ascites.

The disease occurs but rarely in *mares*. The conditions that predispose in this species are not known.

Amniotic plaques, placental mineralization, and avascular chorion

These are normal and their inclusion here is warranted only to avoid confusion to anyone seeing them for the first time. *Amniotic plaques are foci of squamous epithelium on the internal surface of the amnion.* They may or may not be keratinized. They are about 2–4 mm in diameter, flat, and resemble lesions of the poxes. They are especially concentrated on the umbilical stump where they are taller, cylindrical, or papilliform. They seem to be constantly present on the bovine amnion during the middle trimester, and they do also occur in other species but have not received much attention.

The *deposition of mineral*, visible about the small blood vessels of the placenta as white streaks and spots, occurs in many species from about the end of the first to the middle of the second trimester. The degree of mineral deposition is quite variable, and is more extensive in the allantois than in the amnion (Fig. 4.77). It can be distinguished from dystrophic mineralization in that it is not gritty but resembles milk in appearance and texture. There is no indication of why the mineral is deposited nor what, if any, place it has in placental economy.

Metaplastic ossification complete with large multinucleated osteoclast-like cells occurs commonly in the placenta of sows giving birth to normal litters but is rarely seen in other species.

The *avascular chorion,* commonly called the "necrotic tips," is a normal region, which is avascular and avillus, and occurs at the extremities of the chorioallantoic membrane in porcine, ovine, and bovine placentas. It is almost invariably present from the period of elongation to term. Sometimes the region may extend for several centimeters along the chorion. In appearance, it is clearly demarcated from the vascular chorion, varies from white to brown, and is usually wrinkled.

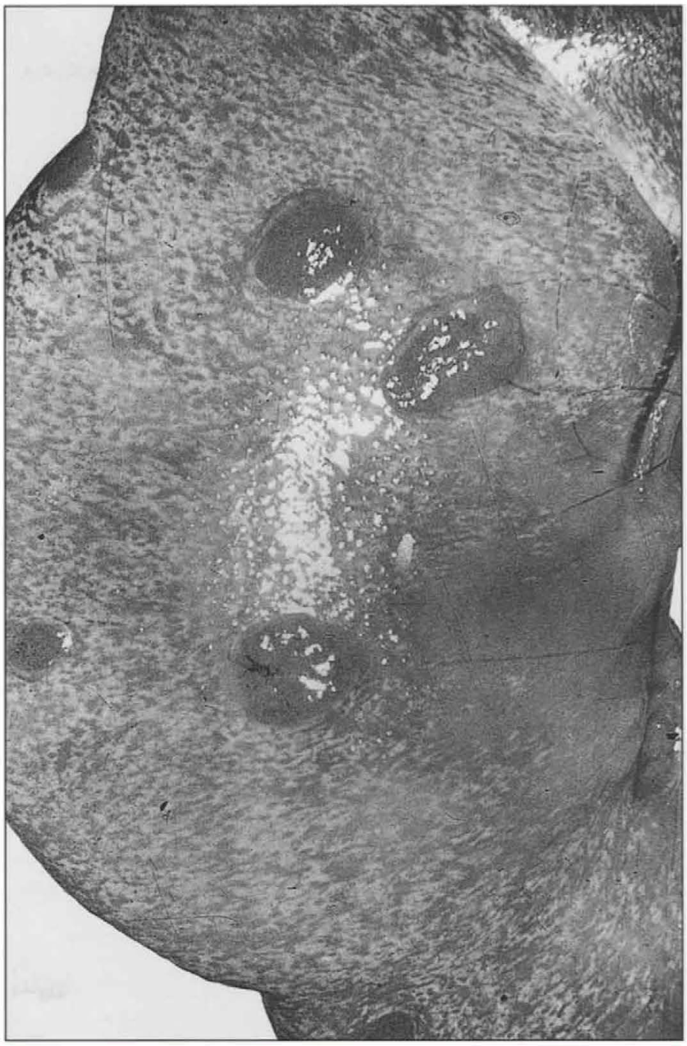

Figure 4.77 Normal mineralization in the placenta of a bovine fetus.

Prolonged gestation

Syndromes characterized by abnormally long gestation periods occur in cattle and sheep. Some of these syndromes have been only partially defined, but in all cases adequately documented, *evidence of fetal anomaly, either anatomic or functional, has been present.* Two of the syndromes in **cattle** have a genetic basis, the trait being governed by autosomal recessive genes, the defective fetus being homozygous.

- The first of these, which is most common in the Holstein and Ayrshire breeds, produces a nonviable large calf after a gestation period which is approximately 2 months longer than normal. The parturition is abnormal; the maternal preparations of relaxation of the pelvic ligaments and filling of the udder are minimal, and assistance is usually necessary. The calves are large, but of nearly normal proportions. They suffer from severe respiratory distress. Death is due to either these respiratory difficulties or uncontrollable hypoglycemia. The *adrenals are hypoplastic* and this is thought to be the lethal defect in the syndrome.
- In the second type of inherited prolonged gestation, which is seen in Guernsey, Jersey, and Swedish Red and White breeds, *fetal monsters* are common. Many of these animals have severe head

anomalies of the cyclopian type, but in some the defect is discrete and consists only of the absence of the pituitary. *Adenohypophyseal aplasia* is common to all of them. These fetuses fail to develop after approximately the seventh month of gestation, and the length of gestation appears to be determined by the viability of the fetus. Some gestation periods last 17 months; at this time, presumably, the placenta can no longer adequately provide for the fetus and the dead fetus, still developmentally immature, is expelled.

Not all syndromes of prolonged gestation in cattle fit this pattern either genetically or anatomically, and sporadic examples of fetuses unable to terminate their gestation occur. These are usually grossly deformed giants with severe brain anomalies; these animals regularly die in utero.

Prolonged gestation occurs in **sheep** as a result of chemically induced teratogenesis. If ewes ingest *Veratrum californicum* on or about day 14 of pregnancy, they may fail to begin labor at term. Pregnancy then continues for weeks beyond term, leading ultimately to rupture of pelvic ligaments and maternal death. The fetuses damaged by the weed have cyclopian deformities and attain giant proportions. Originally, the pituitaries were thought to be absent. It appears that in most cases the gland is displaced in the malformed head.

The functional defects that prevent the various types of fetuses from making their timely contribution to their delivery can now be interpreted in the light of experimental studies. These indicate that, for a fetal lamb to initiate parturition, the fetal hypothalamus, its connection to the pituitary, the pituitary, and the adrenals must be functionally competent. If any of these links is defective, prolonged gestation results. Only hypophyseal absence, however, leads to fetal dwarfism.

An additional syndrome of prolonged gestation has been recognized in ewes that are fed the African shrub *Salsola tuberculata*. The mechanisms by which this plant poisoning interferes with parturition are unknown. They appear to be different from previously reported ones, in that the effects of the plant are not teratogenic, and the intoxication prevents parturition when fed during the last 50 days of gestation. The plant may inhibit fetal hypothalamic-releasing factors.

S. tuberculata is drought-resistant, and the disease occurs when other feed is lacking. The Karakul breed of sheep is the breed raised where the plant is common and is the breed most often affected, but other breeds are susceptible to the toxic effects of the plant. The affected ewes fail to develop normal preparturient udder enlargement, but show no other signs of intoxication.

The fetuses continue to grow and usually initiate parturition 10–20 days past term. At delivery, the affected fetuses are large, lethargic, and suffer a high mortality rate. The pelts are overgrown and worthless, the hooves long, and the teeth erupted. The adrenals of fetuses are hypoplastic and the pituitaries are small and normal granulation of the cells of the adenohypophysis is lacking.

ABORTION AND STILLBIRTH

It will be apparent from the foregoing discussion that diseases of the conceptus may result in death with resorption, fetal mummification, abortion, or stillbirth depending on the age of the conceptus and the species involved, but not all fetal infections result in fetal death. Some viral infections appear to cause little harm to fetuses, at least during certain stages of gestation, and in some the effects are subtle. Many fetal diseases, such as brucellosis of cattle and sheep, epizootic bovine abortion, *U. diversum*, and mycotic fetal infections in cattle are chronic and may lead to the premature delivery of small-for-gestational-age and diseased fetuses.

The list of bacterial and mycotic infections known to produce sporadic abortion is so long as to be nearly valueless because *any bacteremia or systemic fungal infection occurring during pregnancy carries with it a great risk of bacterial or mycotic colonization of fetal chorion.* The entire basis of this susceptibility is not known; however, factors within the conceptus, such as isolation from the maternal immune system, decreased oxygen concentration, elevated temperature, sluggish inflammatory and immune responses, and the provision of preferred nutrients for many organisms, must be important. The organisms involved in fetal infection are the same irrespective of the period of gestation. The effects vary greatly and overall, fetal resistance increases with age. There is some evidence suggesting that bacterial colonization of the fetal membranes does not occur as readily before embryo attachment.

Bacterial and mycotic fetal infections are most common in cattle and horses. There are, however, *important differences in the pathogenesis of the infections in the two species.* Except for the venereal infections early in gestation, bacterial fetal infections in cattle are probably hematogenous in origin. *Leptospira* and *Ureaplasma* infections of cattle, however, may reside in the uterine tube and move to the placenta during pregnancy and perhaps during subsequent infections. Bacterial infections of the equine placenta may arise hematogenously (probably route for nocardioform and some *Streptococcus equi* infections), but are more likely to infect the fetal membranes via the less protective cervix. The route of the infection can usually be determined by examination of the placenta. Transcervical infection involves the chorion adjacent to the internal os of the cervix.

The fetal effects of viral infections depend on the virus and the age of the fetus. Where the effects are known in detail, the pattern is that infections early in gestation are more likely to kill or produce serious teratologic effects; later in gestation, the effects are less severe. There are important exceptions, and the details are not known for most viral infections. Frequent mention is made throughout these volumes to abortion in relation to specific viral diseases. The fact that no mention is made of fetal disease should not be implied to mean that the virus in question is incapable of reaching the fetus or harming it. And, alternatively, the fact that fetal disease is associated with a specific viral disease should not be construed to mean that fetal disease is produced at all stages of gestation, or that, if it is, the resultant fetal lesions are the same throughout the gestation period.

Toxic, nutritional, genetic, and physical diseases are also important causes of reproductive failure and some mention is made of them elsewhere, but often the details are not available. Selected here for description are those infections that characteristically result in abortion as a major manifestation.

Diagnosing the infectious causes of abortion

The diagnostic rate on the causes of abortion, based on examination of samples submitted to veterinary laboratories throughout the world, varies from 5 to 50%. The proportion of abortions that are caused by infection is not known; however, approximately 90% of those abortions in which the cause is determined are assigned to infection. The purpose of this discussion is to assist in maximizing the diagnostic rate on the infectious causes.

Not all of the infectious causes can be recognized by the examination of fetoplacental submissions. The effects of infectious and noninfectious causes may be manifest indirectly through the dam or directly through the placenta and fetus. *Conditions in the dam affecting the fetus and placenta and which may result in abortion include hemoconcentration, circulatory failure, anemia, fever, endotoxemia, and respiratory disease.* With these conditions, no lesion of diagnostic value will be found in the fetus or placenta.

Pregnant animals may contact infectious agents by many routes: through the respiratory tract, vagina, mouth, or, if insect-derived, through the circulation. Some agents may be carried into the reproductive tract with the semen or embryo transfer fluids. In cattle, *U. diversum*, *Bovine herpesvirus 1* (BoHV-1), and *Bovine viral diarrhea virus* (BVDV) may contaminate either of these, and being preserved by freezing and resistant to the antibiotics commonly used, they survive there. In addition, it appears that some agents, such as *Leptospira hardjo,* may be maintained in the uterus or uterine tube over the open period and infect the conceptus as it develops. The role of the changing hormonal influence in the reproductive tract on the multiplication of organisms may be substantial. *Campylobacter fetus* moves from the vagina to the uterus as pregnancy advances and the hormonal influence is altered. Some organisms may multiply in the conceptus for a very long period before abortion. *U. diversum*, for example, may remain in amniotic fluid for up to 117 days before abortion occurs. Similarly, *Aspergillus fumigatus* may multiply in the placenta for at least 25 days before producing abortion, and it is suspected that BoHV-1 remains in the placenta for a prolonged period before invading the fetus.

Cooperation among all parties involved (owner, clinician, pathologist, bacteriologist, virologist) is often necessary to reach a diagnosis. Eventually, other specialists, including nutritionists, toxicologists, botanists, and epidemiologists, may be consulted.

Because the act of abortion rarely points to a definite cause, it is important to collect all information at the first contact. While the history seldom points directly to the cause of abortion, clues may be found that will indicate what needs to be done to determine the diagnosis. Abortion may occur some time after the initiating illness, and therefore health, performance, and travel records become important in suggesting the diagnosis.

As the dam, placenta, and fetus may equally be involved, each should be examined and sampled. In addition, and perhaps more importantly, a representative portion of the remaining animals that have not aborted should be examined.

- Samples should include *serum* from the dam and herd (flock, or kennel), swabs, or samples from the uterus (the caruncle in cattle may be useful), placenta, and fetus.
- If the *placenta and fetus* cannot be quickly and suitably transported in their entirety, samples may be removed and one portion placed in fixative and another in plastic bags on ice for culture.
- Tissues may, in addition, be *frozen* for future culture or testing for agents using one of the many immunologically based techniques presently available.
- Samples from the conceptus for *culture* should include placenta, stomach content, lung, and kidney.
- Tissues essential for *histology* are a sample of the endometrium (caruncle), placenta, brain, eyelid (with conjunctiva), thymus, lung, heart, liver, spleen, kidney, adrenal, and intestine. To be most useful, tissues for histology must be properly fixed or chilled (not frozen) if transport is to exceed 3 hours.

As with the history, it is important to maximize sample collection initially, thereby permitting the use of all the necessary diagnostic aids as the cause is gradually revealed. Samples not required are easily discarded later. The results of serology are more easily interpreted on a herd basis than on an individual animal, and may be particularly useful when samples are collected before pregnancy or at the time of pregnancy diagnosis and again at the time of abortion. This technique has proven very useful in the diagnosis of leptospirosis. A representative portion to establish a baseline titer need only be sampled. Two samples from a dam which has just aborted may contribute little useful information as many agents that subsequently cause abortion have initiated production of a high antibody titer long before abortion occurs. Serum antibody titers are often within the "normal" range at the time of abortion. Interpretation of the significance of antibody titers may be further complicated in that many animals may not respond to the agent with the production of antibody and yet the animal may be carrying the organism and abort because of it. Up to 22% of animals aborting because of *Leptospira hardjo* may not have a significant titer (microscopic agglutination test) at the time of abortion.

It is important not to eliminate a disease from the list of possibilities because of a history of vaccination. Many diseases may occur and result in abortion in spite of previous vaccination, e.g., BVDV and BoHV-1, and of course, vaccination with certain live vaccines during pregnancy may cause abortion. Vaccination titers may be difficult to distinguish from titers due to infection, particularly if exposure has followed inoculation of even a single dose of vaccine. Baseline values need to be established.

Frequently, lesions pointing to the diagnosis may only be present in the placenta. As the placenta is a very large organ, and as much of it may be normal, *the more of the placenta that can be examined, the more accurate assessment of it is likely to be.* It rates in importance for examination equal to both the alimentary and respiratory tracts of an animal after birth. Unless the entire placenta is expelled, at least part of the portion retained internally should be examined, as it often has the most severe lesion and is less contaminated by bacteria from the environment. If the placenta cannot be found, endometrial samples become more crucial and should be requested. Samples may be divided in three and utilized for bacterial culture and histology, and a portion frozen for virology. **The optimal submission includes the fetus and placenta plus serum from the dam**. Serum is best collected at pregnancy diagnosis and then resampled at time of abortion. This method has been found of particular use in the diagnosis of leptospirosis in dairy cows on drylot where the fetus is often not discovered until trampled. Examination of a "fresh" fetus is 53 times more likely to contribute a diagnosis than an autolysed one. Submissions including the entire fetus, placenta, and serum are 4.28 times more likely to result in a diagnosis than where pieces only of the fetus are submitted. Titers of fetal antibody may also be useful in diagnosis of BVDV, *Neospora*, or leptospiral infections.

Some lesions and normal findings that may be confusing will be described briefly. To examine the **caruncle** it should be cut sagittally and the cut surface examined for infarction or suppuration. Infarction is most commonly recognized in mycotic infections but may be caused by a variety of bacteria, including *Brucella* and *Salmonella*. Infarction frequently results in retention of caruncular material by the cotyledon. A variety of bacteria, including *A. pyogenes*, may cause suppurative placentitis. Occasionally, fibrosis of caruncles is seen and may represent normal caruncular maturation or be the result of a chronic infection caused by organisms such as *Yersinia pseudotuberculosis.*

To examine the **chorioallantoic placenta,** it should be completely spread out and inspected carefully for lesions on both surfaces. Lesions in the bovine placenta are commonly observed towards the tip of the pregnant horn and should not be confused with the normal avascular chorion in this site. On histologic examination of hematoxylin and eosin-stained sections of the chorionic villus, a blue finely granular to amorphous material may be observed in the interstitium. This may be glycosaminoglycans, mineral, bacteria, or DNA, and special stains and even close examination will differentiate it. Glycosaminoglycans are considered normal, as is mineral in the early stages of gestation. In the later stages, however, mineral is commonly observed in areas of necrosis and feels gritty on gross palpation.

The trophoblast cells should be thoroughly examined on high power as a variety of bacteria may be phagocytosed, or at least contained, by them. The erythrophagocytic trophoblast has been shown to phagocytose *Brucella,* and the organism has been seen by electron microscopy in the rough endoplasmic reticulum. *Coxiella burnetii* is also found in the trophoblast and can usually be distinguished from bacteria in that the cytoplasm of the cell appears foamy compared to the finely granular appearance of bacteria.

Lesions of variable intensity are usually seen in vessels of the placenta. Discrete necrotizing vasculitis of the endothelial cells in small vessels of the villi regularly occurs with infectious bovine rhinotracheitis infection. Mycotic infections cause very severe vasculitis, resulting in thrombosis and infarction of the caruncle and cotyledon. *Histophilus somni,* while perhaps rare as a cause of abortion, may cause a similar lesion. *Chlamydophila* infections of the placenta may also cause severe vasculitis, but usually without thrombosis. The bacteria-packed vessels in *Salmonella* placentitis are so near the surface that they are easily mistaken for phagocytosed bacteria in trophoblasts.

Lesions of hemorrhage, necrosis, mineralization, and fibrosis may also be observed on the chorionic and allantoic surfaces and are commonly seen with a variety of fungi and bacteria, including *U. diversum.*

The inner surface of the **amnion** may be severely stained with meconium, particularly in chronic progressive infections of the chorion. It is frequently the site of lesions associated with *U. diversum* infection, and is there characterized by multifocal to confluent areas of necrosis, mineralization, and fibrosis, with marked thickening and mild vasculitis being most common. Mycotic and *Mycoplasma* infections may penetrate the chorion and allantois to the amnion and result in a similar lesion.

Discrimination must be used in interpreting the results of cultures derived from samples of fetus, placenta, or even the stomach contents, as organisms may move, or be carried, from the vagina to the conceptus when the cervix dilates during an impending abortion due to another cause. These organisms may rapidly contaminate the placenta, grow in the fetal fluids, and may even be swallowed by a viable fetus, thereby appearing in the stomach contents. *To avoid confusion, vaginal samples should be taken as soon as a vulvar discharge is seen or impending abortion is suspected.* Vaginal discharges from animals with impending abortions are much less likely to be contaminated by extraneous organisms than are samples from an animal that has aborted several days previously.

Observing the relative state of preservation of the fetus may contribute information about the cause. Acute infections, such as those caused by BoHV-1, usually result in the discharge of a severely autolysed fetus, as the fetus is killed rapidly. Chronic infections, (such as *U. diversum, B. abortus, Yersinia pseudotuberculosis,* or *Aspergillus fumigatus*), or other persistent stresses, however, allow the fetus to prepare itself for delivery and hence it is discharged in a fresh state, perhaps small-for-gestational-age, and sometimes alive. *Evidence of the significance of an isolate may only be obtained by histologic examination of certain tissues.*

A few of the less commonly examined tissues which may be useful in making the overall decision about the cause of abortion will be briefly considered. Microscopic examination of the **eyelid** (surface and palpebral conjunctiva) will reveal lesions in about two-thirds of the fetuses aborted due to infectious causes. Lesions are most frequently observed on the conjunctival surface, and vary from a slight infiltrate of mononuclear cells to a severe necrotizing reaction. As in other areas, the cellular infiltrate may be determined by the duration of the infection before death of the fetus. In cattle, *Yersinia* sp., *Ureaplasma,* and mycotic infections are commonly associated with a heavy focal mononuclear cell infiltrate just under the conjunctiva, whereas *A. pyogenes* infection may result in complete loss of conjunctival epithelium, and the accumulation of large numbers of bacteria, but few inflammatory cells, on the surface. Many bacteria, including *A. pyogenes* and *Listeria,* continue to multiply after the death of the animal. BVDV infection may initiate perivascular mononuclear cell infiltration and cause injury to hair follicles. The pattern of follicular hair growth when compared to the age of the fetus may determine the time of infection. Mycotic infections cause folliculitis; however, the lesion is very variable, not only as to its presence but also its severity, and while intracorneal pustules may be seen, frequently either no lesion is observed or traces of inflammation and fungi are only found in the outer sloughing keratinized debris. This material may be lost unless care is taken in sectioning.

Examination of the **brain,** particularly with the discovery of the importance of protozoan infections as a cause of abortion in ruminants, is an essential part of any necropsy examination. Many viral infections manifest their effects in the brain. While the brain often appears soft and unworthy of fixation, and some are literally poured into the fixative, interesting and informative lesions are often found only in this site.

The **lung** *ranks among the most common organs in which to see lesions.* Aspiration of meconium into airways, with or without evidence of an agent, is seen in the terminal phases of many bacterial, and less commonly in mycotic, infections, and is probably related to the rapidity of the development of the lesion and the degree of impairment of placental function. Frequently there will be no local reaction in the lung to the agent and in these the exudate present probably represents aspiration of the agent and inflammatory cells from a placentitis. Many of the inflammatory cells may be maternal in origin. In *U. diversum* and *Bovine parainfluenza virus 3* infections in bovine fetuses, airways may remain relatively clear and alveolar ducts become thickened and the lumina pavemented with many macrophages and a few neutrophils. Severe necrotizing bronchitis may be seen with *Equid herpesvirus 1* infection in horses, whereas BoHV-1 in cattle usually produces only multifocal necrosis and no visible pneumonia.

Examination of the **intestine** contributes much information in some specimens. Sections should be removed from the small and large intestine, with care taken to preserve the content intact. Bacteria may be seen colonizing the luminal content and are used as an indicator of whether or not the bacterial isolate is significant. Terminal swallowing of an agent may transport it to the stomach; however, finding the agent in the intestinal lumen is evidence that it has been in the animal for at least several hours. The fetus swallows amniotic fluid beginning at a very early age, and bacteria and fungi can be easily seen in meconium. In one survey, lesions were observed in association with a variety of agents in 32% of 50 bovine fetuses examined. Lesions varied from mild with *A. fumigatus* to focal areas of necrosis in the mucosa with BoHV-1, diffuse necrotizing colitis with *Listeria*, cryptal necrosis and Peyer's patch lymphocyte hyperplasia with *Bacillus* sp., loss of crypts, and heavy mononuclear and plasma cell infiltrates with *Y. pseudotuberculosis*.

Isolation of different organisms concurrently from the products of abortion makes interpretation difficult. BVDV is commonly detected along with other organisms also considered to be causes of abortion, and in one study was found in 3 of 16 fetuses with *Bacillus* sp., 6 of 30 with *A. pyogenes*, and 17 of 45 with fungal infection. In these animals, immunosuppression associated with BVDV infection may permit the organism to circulate in the dam and localize in the placenta or it may be that, as just stated, the animal was aborting due to BVDV infection and the other organisms were contaminants. In contrast, abortion may occasionally be classified as infectious because of histologic lesions observed, but where no organism is identified. Failure to grow the organism may be due to improper handling of the samples or destruction of the organism in severely autolysed fetuses.

Portions of *chilled kidney* are useful for the fluorescent antibody detection of BoHV-1, BVDV, and *Leptospira*. *Stomach content* is useful for bacterial or mycological culture and direct examination for bacteria, fungi, and rickettsia (*Coxiella*). In some diagnostic laboratories, all samples of stomach content and impression smears of placenta are examined using a modified acid-fast stain. Using this stain and others, an experienced microbiologist can distinguish a variety of organisms. Certain organisms are extremely fragile, and care in handling samples becomes very important. Samples to be cultured for *U. diversum*, for example, should be collected aseptically, chilled to 4°C and delivered to the laboratory immediately. Leptospires may be equally fragile.

Fetal serum or thoracic fluid samples for antibody detection may be collected but the antibody titers, as in the dam, must be interpreted with caution. The fetus is capable of responding to a variety of agents with antibody production relatively early in gestation, and the presence of specific antibody in fetal fluids may be considered presumptive evidence of fetal infection. It has been shown, however, at least in sheep, that placental vascular damage may allow antibodies to cross the placenta from the dam to the fetus, thereby making interpretation difficult. When antibody passage occurs, concentrations in the fetus will presumably be lower than in the dam. Fetal antibody detection has been useful in diagnosing fetal BVDV, and leptospiral infections in third-trimester fetuses.

Bacterial causes of abortion

Brucellosis

Bacteria of the genus *Brucella* are small, gram-negative bacilli or coccobacilli that are strictly parasitic, prefer the intracellular habitat, and produce in animals chronic infections with persistent or recurrent bacteremias typically manifested by abortion.

Three classic species of *Brucella* were described and defined originally largely on the basis of host of origin – ***B. melitensis***, goats, ***B. abortus***, cattle, and ***B. suis***, swine – but now by biochemical and serological reactions. The differences between the species are slight and quantitative rather than qualitative, and the number of biotypes within each species is large. This has led to the recommendation that all should be considered a single species, *B. melitensis*, and that present species and variants with fixed properties be regarded as biotypes of the one species. This suggestion has much to recommend it. The current nomenclature is confusing to the nonspecialist. However, most of the old truths still apply; the disease in cattle is caused by strains of *B. abortus*, the disease in sheep and goats by *B. melitensis*, and *B. suis* is found chiefly in swine. Cross-infections do occur and almost all domestic species are susceptible. But changes in the nomenclature will not solve the fundamental problem posed by the tendency of organisms of the genus to acquire new characteristics and infect new hosts. The animals in which the new varieties of organisms have been discovered have usually been hosts not previously included in the reservoir system of the genus. Examples of this phenomenon are the discovery of organisms now known as *B. suis* type 2 in hares, *B. neotomae* in wood rats, *B. ovis* in rams, and *B. canis* in dogs. The generation of new features is presumably the result of evolutionary forces; why the changes are occurring so rapidly is unknown. It seems likely that what has been done in the laboratory to change speciation has been done in nature, and that rapid evolutionary changes will continue to be the norm of the genus. And this in turn will continue to pose identification problems and disrupt control and eradication programs.

The biological similarities among the various species and biotypes of *Brucella* are in keeping with the remarkable similarities in the diseases produced in the different hosts by the various strains of the organism. Infections by any of these organisms of the genus *Brucella* are, initially at least, systemic, and relapsing bacteremic phases are well-established events in the persisting infections. Localization and persistence of infection may occur in many organs, perhaps to a greater extent with *B. suis* than with the other species. Some organs, however, notably the genitalia and placenta, are noted for the regularity with which they develop intense persistent foci of infection.

Bovine brucellosis caused by *Brucella abortus*

Brucellosis occurs in cattle in most parts of the world. In some countries the incidence of the disease is low, either because of measures taken to prevent its entry or to eradicate it but, where the disease is endemic and uncontrolled, the incidence may approach 20–30%.

The usual source of infection for cattle is an aborted fetus or placenta, or contaminated uterine discharges, and the usual route of infection is alimentary. Infection can also occur per vaginam, via the conjunctiva, and through the broken or unbroken skin. The relative importance of these latter routes is not known. Coital infection can occur but is uncommon, especially if genital infection in the male is longstanding, possibly because fewer organisms are excreted in semen from chronic lesions than from early lesions in the genitalia of bulls. Infection can be transmitted at artificial insemination if semen from infected bulls is used. Irrespective of the route of infection, the development and establishment of infection are probably comparable and will depend on the age and reproductive status of the animal, its inherent resistance, and on the dose and virulence of the infecting strain of the organism. Young cattle are relatively resistant up to about the age of puberty. They can be infected by the usual routes and means, including the ingestion of milk in which the organisms are intermittently excreted. Calves normally throw off the infection in the course of a few months.

Once infection is established in sexually mature animals, females especially, it tends to persist indefinitely. Some, perhaps many, will recover completely, but which ones will, and when they will, cannot be predicted. The organisms extend quickly to the lymph nodes regional to the point of entry, and there they provoke acute lymphadenitis. The inflamed nodes are enlarged, often much so, hyperplastic with no clear corticomedullary distinction, and frequently bear small or large medullary hemorrhages. The sinuses are infiltrated with neutrophils and eosinophils; germinal centers and proliferative activity become obvious; and there is slow but remarkable accumulation of plasma cells in the medullary sinuses. The changes in the regional nodes take some weeks to develop fully, and they persist for a prolonged period. There is no fibrosis or necrosis in the nodes.

The infection may be overcome in the regional nodes, but once established, it is expected to spread during the phase of acute regional lymphadenitis. Spread is chiefly hematogenous and bacteremia may persist for several months, the duration of persistence apparently depending on the susceptibility or resistance of the host. As the infection becomes chronic, bacteremia becomes intermittent, ceases in some animals, and recurs irregularly for at least 2 years in 5–10% of animals. Also, it tends to recur at parturition. It might be expected that the bacteremic episodes would result in localization and persistence of the organism in many tissues but, curiously, localization is largely restricted to the spleen, mammary glands, mammary lymph nodes, and pregnant uterus of the female, and to the lymphoid tissues, testis, and accessory glands in the male, and such localizations occur in the early bacteremic phases. The organism has little or no predilection for the kidney (although microscopic interstitial nephritis may be present), ovary, bone marrow, or mesenteric lymph nodes, and appears not to be excreted in the urine or feces. Localization does occasionally occur in synovial structures to produce purulent tendovaginitis, arthritis, or bursitis, but whether localization and persistence occur in synovium which is healthy is not clear; some pre-existing inflammatory changes may be necessary.

Infected animals, almost without exception, excrete *B. abortus* in the colostrum. Thereafter, excretion of the organism in milk may cease, but frequently it continues, although intermittently, throughout the period of lactation. Organisms excreted in milk are an important source of infection for children; and also for calves, but they recover without significant effect. It is still not clear whether and to what extent *B. abortus* causes anatomical changes in the mammary glands. This must be expected, but they must also be mild and difficult to distinguish from the focal inflammatory reactions commonly present in mammary glands. Dense infiltrations of the interstitial tissue by plasma cells, lymphocytes, and histiocytes, and exudation of neutrophils in acini probably constitute the usual changes. The mastitis is focal and not attended by gross changes. The cellular content of milk is increased.

B. abortus has special affinity for the pregnant endometrium and fetal placenta to which it spreads hematogenously during the initial or later bacteremia. Experiments using *B. abortus* in goats have shown that the organism is carried by the bloodstream to the periphery of the caruncle, where at the extremities of the maternal villi capillaries leak into the narrow space (hemophagous organ) adjacent to the fetal erythrophagocytic trophoblast of the chorion. Either cells of the erythrophagocytic chorionic trophoblast phagocytose the *Brucella* organisms, or they invade; regardless, they multiply and spread via the uterine lumen and endocytosis, or by cell-to-cell transfer, to the rough endoplastic reticulum of the adjacent chorionic trophoblast cells. They multiply here and spread to the fetus following ulceration of the trophoblast and invasion of the fetal chorionic villi. The process may be similar in the bovine caruncle where hematomas appear at the ends of maternal septa late in gestation.

Gross lesions *in the placenta are characteristic but not pathognomonic;* similar lesions of less or equal severity may be caused by other bacterial infections, and fungi produce similar lesions, usually of greater severity. There is considerable variation in the severity of the placental lesions, and this is reflected to some extent in the course of the local infection. If the lesion is severe, abortion or premature birth is the likely outcome, and if the lesion is of minor severity, the calf may be delivered normally at term and be viable or nonviable. The intrauterine lesions apparently progress very slowly, because an interval of many months may elapse between infection and abortion or normal birth. Abortion occurs most often in the seventh and eighth months of gestation. Once the infection localizes in a pregnant uterus, it almost certainly remains there and remains active until the fetus and placenta are delivered and for some time thereafter. The nonpregnant uterus is not particularly susceptible to *B. abortus*, and following abortion or parturition, the organism is cleared from the uterus in a few weeks, or longer in some cases.

The external appearance of an infected pregnant uterus is normal. Sometimes the placenta is normal. Typically, *between the endometrium and chorion in the intercotyledonary area, there is more-or-less abundant exudate* that is odorless, dirty yellow, slightly viscid and slimy, and which contains gray-yellow, pulpy floccules of detritus. The fetal membranes and the umbilical cord are saturated with clear edema fluid, and the membranes may be 1.0 cm or more thick. The fetal fluids are usually normal, although occasionally fluid in the amnion is viscid and stained with meconium as the lesion extends.

The placental lesions are not uniform; some cotyledons may appear more-or-less normal and others will be extensively necrotic, while still others are diseased to intermediate degrees; similarly, the intercotyledonary placenta varies in the extent to which it is changed, lesions being most prominent adjacent to the cotyledons. Affected areas of intercotyledonary placenta are thickened with yellow gelatinous fluid, opaque and tough, and the normal smooth glistening surface takes on an appearance resembling yellow to gray Morocco leather with, on the surface, a patchy coagulum of inflammatory exudate and desquamated, degenerate epithelial cells. Affected cotyledons or portions of them are necrotic, soft, yellow-gray, and may be covered with the sticky, odorless, brown exudate that is usually referred to as resembling soft caramel candy.

Histologically, edematous placental stroma contains increased numbers of leukocytes, largely mononuclear but with some neutrophils. The chorionic epithelial cells are stuffed with bacteria (Fig. 4.78), and many of them, with their inhabitants, desquamate into the uterochorionic space. The organisms in intact epithelial cells are coccoid, but free in the exudates; they assume a more elongate form even while still contained within the ghosts of dead epithelial cells. Over the placentomes, the same sort of placentitis is present, but the parasitism is not so extensive in the epithelial cells covering the cotyledonary villi, except at their base, or in the epithelium lining the caruncular crypts, although many of the syncytial trophoblastic cells may be necrotic. The intervillus portions of the placenta, the so-called placental arcades, are quite severely affected, and exudate accumulates between the arcades and the expanded outer extremities of the maternal septa. There is normally some placental exudate and minor hemorrhage in these spaces, but this is greatly exaggerated in placentitis and contains infiltrated leukocytes, epithelial debris, and bacteria. The maternal portions of the placentome are not much involved except for the expanded ends of the maternal septa where these are bathed in the exudate of the placental arcades, and in consequence, become denuded and superficially necrotic. Beneath the necrotic tips of the maternal septa, there is more-or-less dense infiltration of leukocytes and prominent productive inflammation, the

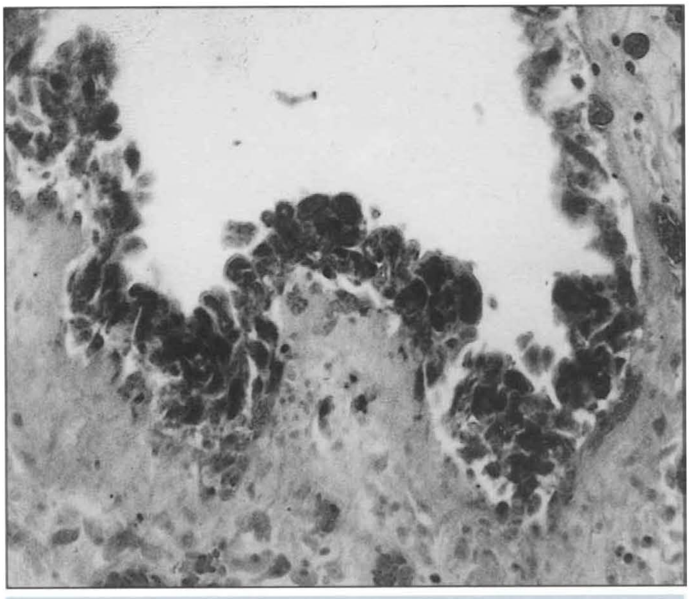

Figure 4.78 Colonies of ***Brucella abortus*** in cells of chorionic epithelium.

fibrosis extending some distance along the sides of the septa. Inflammatory enlargement of the terminal portions of the maternal septa produces an increased degree of placental interlocking, and probably contributes to retention of the placenta. Adhesions, in the usual sense of connective-tissue fusion, between placenta and uterus do not occur. The endometrium is relatively unscathed in the early infections. The zona basalis shows some increase in lymphocytes and plasma cells, and there may be scattered microscopic granulomas of epithelioid cells. Even the intercaruncular epithelium may not be overly disturbed. Later, there is severe endometritis.

(For a discussion of lesions in bulls caused by *B. abortus*, see Vol. 3, Male genital system.)

The **fetus** is usually somewhat edematous with blood-tinged subcutaneous fluid. The same fluid is present in excess in the body cavities and the dorsal retroperitoneum. The normal abomasal content of a fetus is clear, translucent, thick, and viscid; in brucellosis, it often becomes very turbid, of a lemon-yellow color, and flaky. *The important fetal lesion in brucellosis is pneumonia that is present to some degree in most fetuses aborted in the last half of pregnancy.* The lungs may appear grossly normal, but histologic examination reveals scattered microscopic foci of bronchitis and bronchopneumonia (Fig. 4.79). When severely affected, the lungs are enlarged and shaped to the thoracic contour, firm on palpation, reddened on the pleural surface or hemorrhagic, and with fine yellow-white strands of fibrin on the pleura. Microscopically, there may be any stage from the minor changes mentioned through a well-developed catarrhal bronchopneumonia to the fibrinous variety. The predominant inflammatory cells are mononuclear, although many immature and mature neutrophils may be present in some areas. The septa may be edematous and the perivascular lymphatics infiltrated with leukocytes. *By the time the placentitis has advanced to an extent where abortion is inevitable, acute diffuse endometritis, without histologic specificity, has developed.* Variable lesions in the fetus include necrotizing arteritis, especially of pulmonary vessels, focal areas of necrosis, and granulomas with giant cell formation in lymph nodes, liver, spleen, and kidney. The organism may be identified by culture, immunofluorescence, or immunohistochemistry.

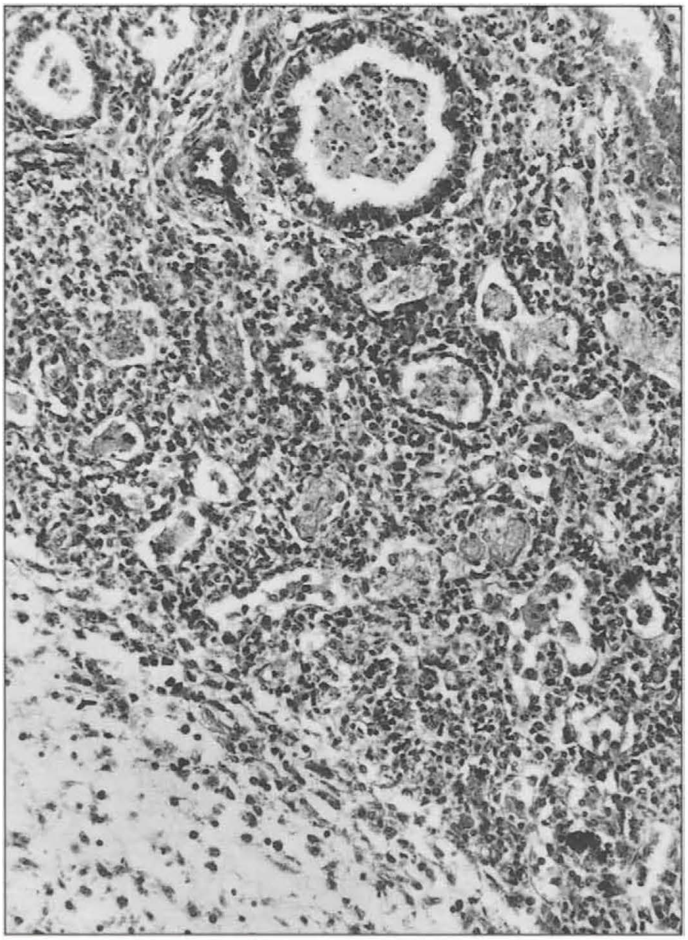

Figure 4.79 Pneumonia due to brucellosis in a bovine fetus.

Brucellosis in swine, caused by *Brucella suis*

Pigs are susceptible to *B. melitensis,* and slightly susceptible to *B. abortus*. The disease is usually caused by *B. suis*, and this organism presents important problems in many countries. *There are some differences in the diseases produced by B. suis and B. abortus, and these depend largely on the frequency with which B. suis in swine produces focal granulomatous lesions with coagulative necrosis, the affinity of this organism for the skeleton and joints, and its tendency to remain in granulomatous foci in the nonpregnant endometrium.*

The early stages of the pathogenesis of the infection are comparable with the early stages of bovine brucellosis. Infection can occur by the same variety of routes, but, *in swine, brucellosis is chiefly transmitted by coitus.* Boars are as readily infected as sows, and most infected boars develop lesions in the testes or accessory genitalia, from which the organisms are shed in the semen, often for life. They may also be shed in the urine from a focus of infection in the bladder. Infected females may discharge the organism from the uterus for up to 2.5 years. Suckling piglets can be infected, although they are less susceptible than weaners or adults, and although most infected piglets cast off the infection, a few carry the infection into adulthood.

With the development of lymphadenitis regional to the point of entry, the infection becomes bacteremic. *The bacteremia may be transient or persist for many months or even for some years.* Localization may occur in many organs, but especially in the male and female genitalia, the skeleton, including the vertebral column, synovial structures, mammary glands, lymph nodes, spleen, liver, kidney, bladder, and even in the brain.

B. suis can grow and multiply in phagocytes, and the typical granulomatous lesion begins with the accumulation of histiocytes and epithelioid cells. Perhaps as a response to developing hypersensitivity to the organisms, as the lesion enlarges, caseous necrosis occurs centrally and fibrous tissue forms a capsule. The granulomas enlarge progressively, and the necrotic tissue attracts neutrophils. Giant cells are absent or scarce. Calcium salts may be deposited in the necrotic foci.

Articular lesions caused by B. suis are quite common. They begin as a synovitis and chiefly affect the compound and large joints of the limbs. The reaction is purulent or fibrinopurulent. *Osteomyelitis in this disease is typically vertebral* (or usually observed there). As with other causes of osteomyelitis, localization is typically in the vertebral epiphyses of the lumbar region. There is, however, an unusual tendency to involve and destroy the intervertebral cartilages. The smaller bony lesions are typically granulomatous with dry caseation necrosis, but the necrotic cores of larger lesions may liquefy and the suppurative reaction extends to the meninges or fistulae to produce paravertebral abscesses.

In the uterus and uterine tubes, there are often conspicuous and characteristic lesions, which are not dependent on an association with pregnancy. They have been referred to as *miliary uterine brucellosis* and, as the name infers, there are few or very many pale yellow nodules with an average diameter of 2–3 mm seeded in the mucosa. When the nodules are numerous, they may coalesce to form irregular plaques and then are associated with thickening of the uterine wall and stricture of the lumen. The same lesion is usually also present in the uterine tubes, where obstruction results in pyosalpinx. Incised, a small quantity of caseous exudate can be expressed from the nodules. Small, red, flat, and irregular granulomas are often scattered over the surface of the supporting ligaments; grossly, they resemble fetal fat and are easily overlooked. There is some stromal fibrosis and diffuse cellularity in the tubes and endometrium due to infiltrated plasma and lymphoid cells. In addition, well-developed and multiple hyperplastic lymphocytic nodules are evident. There are few neutrophils in the stroma, but with the mononuclear cells, they can be seen pushing their way through the epithelium to collect in abundance in the lumen of the uterus and tube and in the more superficial glands. The glands are dilated and the leukocytes are enmeshed in strands of mucin and mixed with amorphous globs of mucus. The deeper glands are cystically dilated with attenuated epithelium, serous or thin mucinous content, and few, if any inflammatory cells. The epithelium lining the lumen and superficial glands is in part retained, in part desquamated, and in part shows the development of a remarkable degree of squamous metaplasia, even to the development of rete pegs and intercellular bridges. The organism is not visible in the lumen.

Abortion usually occurs between the second and third month of pregnancy, but the incidence of abortion is relatively less than in the bovine disease; *there is also a high incidence of stillborn and weak piglets born at term,* and probably also a high incidence of early undetected embryonic deaths. The placenta may be retained. The specific uterine lesions of porcine brucellosis are described above. Apparently, the miliary lesions may develop during pregnancy to a superimposed diffuse catarrhal type of endometritis with patchy congestion, hemorrhage, and edema and a small amount of creamy-pink catarrhal exudate that contains large numbers of organisms. The fetal placenta may not show conspicuous changes, but as a rule, it is congested with small hemorrhages and patchy edema. Usually too, there is a thin layer of exudate that is slimy, gray-yellow, or gray-brown, like mucopus. It is more copious than the secretion normally present in the interplacental space, and smears from it show numerous free organisms and many epithelioid cells, presumably chorionic, which contain clumps of bacteria. The fetus shows subcutaneous edema, which is especially prominent about the umbilicus, and effusions into the body cavities. The edema fluid is often blood-stained. The stomach contents may appear normal or be slimy, turbid, or yellowish and may contain small flakes like curd.

Brucellosis in sheep, caused by *Brucella ovis*

A *Brucella* mutant, *B. ovis*, which was identified less than 35 years ago, causes a specific form of epididymitis in rams in most parts of the world in which sheep are raised. The organism also causes placentitis in pregnant ewes, but *epididymitis is the more common and important manifestation of the infection*, and the main discussion of the disease is included in Vol. 3, Male genital system.

There are probably as many modes of transmission as there are for the *Brucella* in general, but in this disease, *the coital route is important; infected rams excrete large numbers of the organism in the semen.* The infection passes through a stage of generalization, but the disease is never generalized. The organism is a humble one and not very virulent. It grows abundantly but harmlessly in the incubated egg, and survives for a long time in the rat testis without provoking anything. Even the epididymitis of rams is largely an indirect effect. The epididymal lesion produced by the organism, possibly immune-mediated, is a modest one, but it does predispose to sperm stasis and extravasation, which produce the *characteristic chronic granulomatous epididymitis*, by which the disease is recognized. In contrast to the organism's nonpathogenic nature in the nonpregnant ewe, *the organism readily parasitizes the placenta and produces abortion*; this is not common, although it may be important in individual flocks. While the manifestations of infection in both ewes and rams are solely genital, the organism can be cultured in large numbers from other organs in which it does not, however, produce lesions.

The *placenta* is grossly edematous, being thickened to 2–5 cm by gelatinous fluid. *Periarteritis and arteritis are distinctive features*, as in most forms of placentitis. The amnion is adherent to the chorioallantois and thickened in patches. The intercotyledonary placenta has plaque-like thickenings, which may coalesce to resemble yellow-white chamois leather (Figs 4.80, 4.81). Diseased cotyledons may become partially detached; they are firmer than normal, enlarged, and pale yellow. There is extensive necrosis of the epithelial elements of the cotyledons with edema and cellular infiltration of the stroma. Organisms in abundance inhabit the epithelial cells of the chorion.

Most lambs are alive at the commencement of parturition, but mummification or progressive autolysis is also common. As usual, the fetus tends to be moderately edematous, the fluid blood-stained, and that in the serous cavities may contain flecks or strands of fibrin. When present, calcified plaques on the walls, soles, or both, of the hooves and accessory digits are characteristic. *The fetus shows little histological evidence of systemic infection*, even though the gastric contents may be heavily infected. Mild pneumonic alterations and lymphadenitis, especially in anatomical association with the lungs, may be present together with the development of germinal centers and plasma cells in nodes and spleen. Acute interstitial nephritis, particularly about the corticomedullary junction, and inflammatory infiltrates in portal triads are common.

The nonpregnant uterus is insusceptible to the infection. Infection of the fetus may be produced experimentally at any stage, but following systemic exposure, as per conjunctiva, the period of greatest susceptibility to intrauterine localization is from about 21 to 90 days of pregnancy.

Following artificial exposure, there is a lag of 2–3 weeks before bacteremia develops, and the bacteremic phase, in rams and probably in ewes, lasts about 2 weeks. Breeding ewes to rams with open epididymal infection is more likely to result in infertility than abortion. The routes of natural exposure of pregnant ewes are not known. Placental localization is followed by slow development of the intrauterine infection, and the pregnancy may survive for 2–3 months after first being infected.

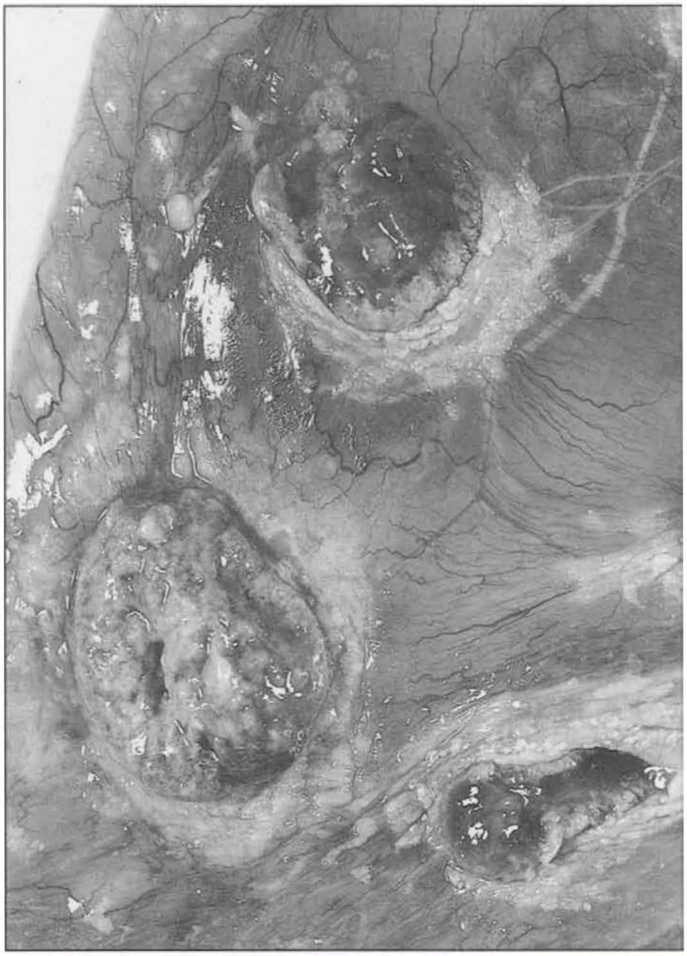

Figure 4.81 Details of **pericotyledonary placentitis** caused by *Brucella ovis* in a sheep.

Brucellosis in sheep and goats, caused by *Brucella melitensis*

B. melitensis is the principal cause of brucellosis in sheep and goats, although natural infections with *B. abortus* occur occasionally. Brucellosis in goats and sheep is prevalent in countries bordering the Mediterranean, in the Near East, and in South America.

In most respects, *the caprine disease resembles bovine brucellosis*, but the disease in sheep is usually less protracted and spontaneous recovery is fairly common in a few weeks or months. In the early bacteremic phases, goats may suffer severe illness and even die, but many infections are asymptomatic. The early signs of the disease may be referable to acute mastitis with palpable nodules in the gland and a secretion that is clotted and watery. The organism is excreted in the milk, usually only for a few weeks in sheep, but often for several months or even some years in goats.

As is usual for ruminants, *abortion may be the only sign observed and it tends to occur late in pregnancy*. The uterine and vaginal discharges after pregnancy or parturition contain large numbers of organisms. Abortion or stillbirth may terminate successive pregnancies.

Brucellosis in dogs, caused by *Brucella canis*

B. canis was first isolated and recognized as a cause of abortion and epididymitis in dogs in 1966. The disease was identified in Beagle colonies in North America at that time. Since then, it has been found in many parts of the world and in a variety of breeds. However, accurate incidence rates are not available; in the USA, where the infection is widespread, the reported incidence rates range from 0.5% to 5%.

The disease is caused by a mucoid strain of *Brucella* that shares biochemical features with *B. suis*. Because of the mucoid nature of the organism, it does not possess the smooth (0) antigens of *B. abortus* or *B. melitensis*. As a consequence, the conventional brucellosis test antigens that are used for diagnosis of the disease in other domestic species are ineffective in the diagnosis of *B. canis* infections.

Transmission of the disease can be *by ingestion* of infected vaginal discharge after abortion or *venereally* by infected seminal fluids. The seminal fluids may remain infected for months. Pregnant bitches may abort after 30 days of gestation, but *most abortions occur after 50 days. Testicular degeneration and epididymitis are the usual manifestations of the* *disease in male dogs*. In response to the discomfiture of the epididymitis, the dogs frequently lick the scrotal skin, producing severe ulcerations. Persistent bacteremias are common in many dogs that show no signs of disease. Bacteria have been recovered from the blood for periods as long as a year, even though high agglutinating titers were maintained throughout the bacteremic period. The nongenital lesions consist initially of nonspecific enlargement of the retropharyngeal and mandibular lymph nodes. Later the lymph nodes throughout the body may be enlarged due to diffuse hyperplasia of lymphocytes and macrophages. The aborted fetuses may be dead or alive when expelled, but live fetuses usually die within a few hours or days. Pneumonia, endocarditis, and hepatitis are observed in the infected fetuses.

Focal necrosis is prominent in the chorionic villi and many of the trophoblastic epithelial cells are laden with bacteria. In the bitch, serosanguineous to gray-green vaginal discharge may be evident for 1–6 weeks following abortion, and provides a source of infection for other dogs.

Brucellosis in other domestic species

Brucella abortus or *B. suis* is regularly found in the bursal lesions described elsewhere as "**poll evil**" and "**fistulous withers**" (see Vol. 1, Bones and joints). There are other isolated reports of suppurative skeletal or synovial lesions in horses caused by these organisms.

Whereas **cats** are resistant to natural infection with *Brucella* spp., **dogs** are relatively resistant to the classical strains of *Brucella*, but natural infections caused by all three species of the organism do occur. The majority of such infections are asymptomatic and detected serologically. Orchitis and epididymitis have been observed. Other lesions described in dogs with brucellosis, chiefly minute granulomas in liver, kidney, and lymph nodes, are neither specific nor necessarily related to the infection.

Campylobacter infections of the genital tract in sheep and cattle

Infections caused by *Campylobacter* species are common and widespread in humans, cattle, sheep, swine, and chickens and also occur occasionally in dogs. In sheep and cattle, diseases caused by these organisms were previously grouped under the title of "vibriosis," given their classification in the genus *Vibrio* at that time. The principal patterns of disease are *genital*, characterized by infertility or abortion, or *intestinal*, characterized by enteritis and diarrhea.

- *C. fetus* subsp. *venerealis* (previously *V. fetus* var. *venerealis*) causes a true genital infection and is an important cause of infertility in cattle and can cause abortion in cattle and sheep.
- *C. fetus* subsp. *fetus* (previously *V. fetus* var. *intestinalis*) is a common resident of the ovine and bovine intestine and can cause abortion in both species but does so more commonly in sheep.
- *C. jejuni* (previously *V. jejuni*) is a common inhabitant of the intestinal tract in sheep and cattle and may cause enteritis in humans and occasionally animals. It frequently causes abortion in sheep and less often in cattle, although heavy losses in individual cattle herds do occur.

Genital infection of cattle caused by Campylobacter fetus subsp. venerealis

The disease in cattle due to *C. fetus* subsp. *venerealis* is a specific venereal disease, transmitted by coitus. Infected bulls may carry the organism indefinitely in the preputial cavity, although some recover spontaneously. Bulls do not become permanent carriers until they are at least 4 years of age, and most do not become readily infected until they are 5–6 years old. Epithelial crypts develop in the penile mucosa with advancing age and provide a favorable habitat for the bacteria. This also appears to be the natural habitat for these organisms, and once the infection is established in these older animals, it tends to be retained permanently as a locally innocuous surface contaminant together with the nonpathogenic *C. sputorum* subsp. *bubulus*. The organism may also survive for long periods without producing lesions on the surface of the bovine vagina, but not in the uterus. Infected cows develop immunity and control the infection. *The outstanding feature seen with the infection is not abortion but temporary sterility or repeat-breeding with prolongation of the interestrual periods.* It is probable that the delayed return to estrus is the consequence of early embryonic death following fertilization and embryo attachment. Detectable abortions occur at any time but chiefly about the fourth to sixth month of gestation. The placenta is not usually retained.

The endometrial lesions in cows that are repeat-breeders are mild, and consist of lymphocytic infiltrations and nodules and scattered cystic glands. Aborted placentas are often autolysed, indicating that fetal death occurs some time before expulsion. *Placental lesions resemble those in brucellosis but are less severe.* The intercotyledonary placenta is edematous, opaque, and may be leathery; there is a diffuse infiltration of cells, which are mainly histiocytes. Diseased cotyledons are yellow and pulpy; many have yellow necrotic villi at the margins and in others these are scattered throughout. There may be dense accumulations of neutrophils among the denuded villi and in the stroma. The degree of placentitis is quite variable and may be inconspicuous. The parasitism of the chorionic epithelium that is characteristic of *Brucella* occurs but is less evident in placentitis caused by *C. fetus* subsp. *venerealis*. *Lesions in the fetus are nonspecific.* There are commonly blood-stained effusions in the subcutis and body cavities with loose deposits of fibrin on the serous membranes. The normal colorless thick viscid mucus of the stomach content becomes yellow, very turbid, and flaky.

Genital infection of sheep and cattle caused by Campylobacter jejuni or Campylobacter fetus subsp. fetus

The chief manifestations of these Campylobacter infections in sheep are late abortion, premature birth, and the birth of weak lambs. There is not usually retention of the placenta or sterility. Occasional maternal deaths occur as a result of metritis. *Infection is not synonymous with abortion*, as infected ewes may deliver infected but clinically normal lambs.

Transmission of *C. jejuni* most often occurs by the oral route, and fecal contamination of water supplies is relatively frequent. The organism is carried in the intestinal tract of poultry, and it is a commensal of cattle, sheep, and swine. The organism is also a frequent inhabitant of the intestine in dogs and cats and many rodents.

When strains of *C. fetus* subsp. *fetus* isolated from feces or bile are given orally to susceptible sheep, there is transient bacteremia followed by localization in the gut and bile, and the infection can spread by contact between sheep. In pregnant, nonimmune ewes, localization also occurs in the uterus. Surface (S)-layer proteins appear to be essential for colonization and/or translocation of *C. fetus* subsp. *fetus* to the placenta. With both of these *Campylobacter* species, the genital infection is primarily an intestinal infection; transmission is by ingestion, and *uterine localization is an accidental outcome of a brief bacteremic phase in a nonimmune sheep.* The incidence of abortion will depend on the number of ewes pregnant more than 1 month and on their experience with the infecting strain. Immunity following infection or abortion usually lasts for 2 years; however, if other strains are introduced, they may cause abortion, as cross-protection between strains is incomplete. This also applies to vaccination strains.

The abortion rate in natural outbreaks varies between 5% and 70% but is usually about 25%. *Aborted fetuses may have only nonspecific edematous changes; however, some have rather specific hepatic lesions.* Affected livers have few or many light tan areas, from 1–2 mm up to 1–2 cm in diameter, and randomly distributed (Fig. 4.82). Frequently they have a "target pattern" with a more or less distinct, slighty raised white outer rim and a depressed tan inner zone. The abdomen is frequently distended with fluid, fibrin, and the enlarged liver. If the lamb has lived a while before succumbing, these lesions must be differentiated from those of putrefactive origin and from the focal necrobacillary hepatitis of umbilical origin. Histologically, *the lesion is multifocal necrotizing hepatitis*, the necrotic region represented by the tan area and the outer rim by cellular infiltrate and necrosis (Fig. 4.83). There is frequently bronchopneumonia with large numbers of neutrophils in major airways and alveolar ducts. Small renal cortical hemorrhages may also be present.

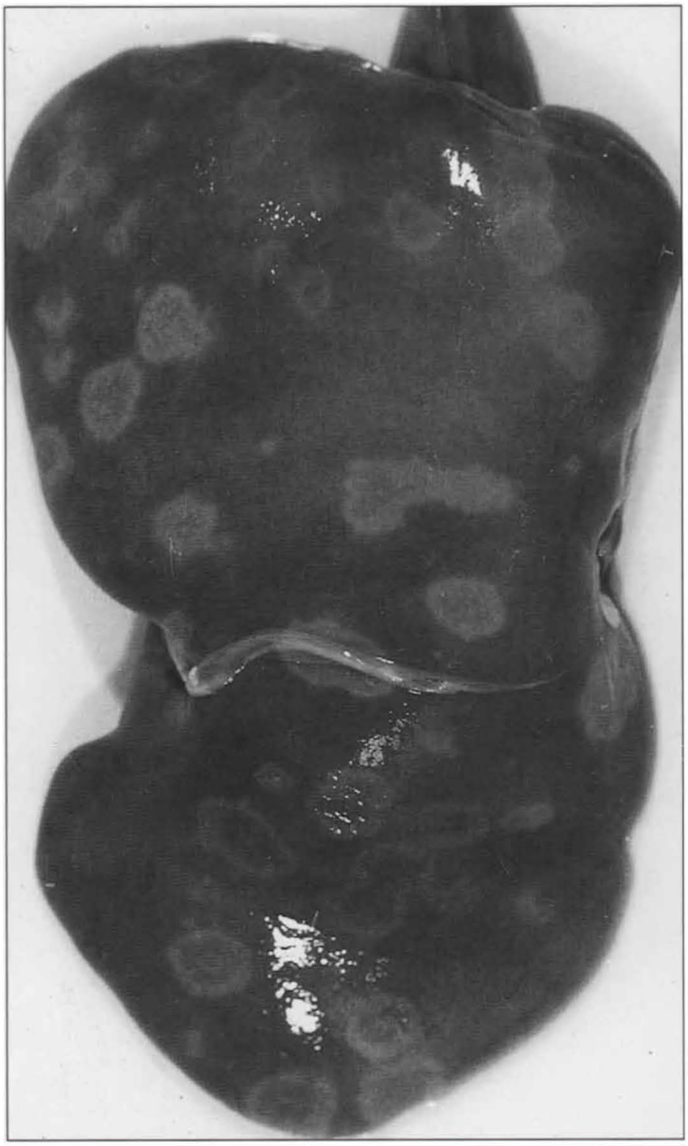

Figure 4.82 Focal hepatitis caused by *Campylobacter fetus* in a fetal lamb.

The cotyledons are enlarged, pale yellow to tan, dull and pulpy, and covered with brown exudate. The chorionic stroma is edematous and infiltrated with leukocytes, which are mainly histiocytes. There is frequently vasculitis. There is mild or acute endometritis with rather more prominent inflammatory exudation in the caruncular septa. The placental lesions are more severe over the placentomes than in the intercotyledonary areas, and are qualitatively similar to the lesions described in the placenta in bovine brucellosis.

Diagnosis *is based on the typical hepatic lesions and demonstration of the organism.* Distinctive organisms may be observed in smears of abomasal content or of affected cotyledons and show up well with special stains. Dark-field or phase-contrast microscopy may be used

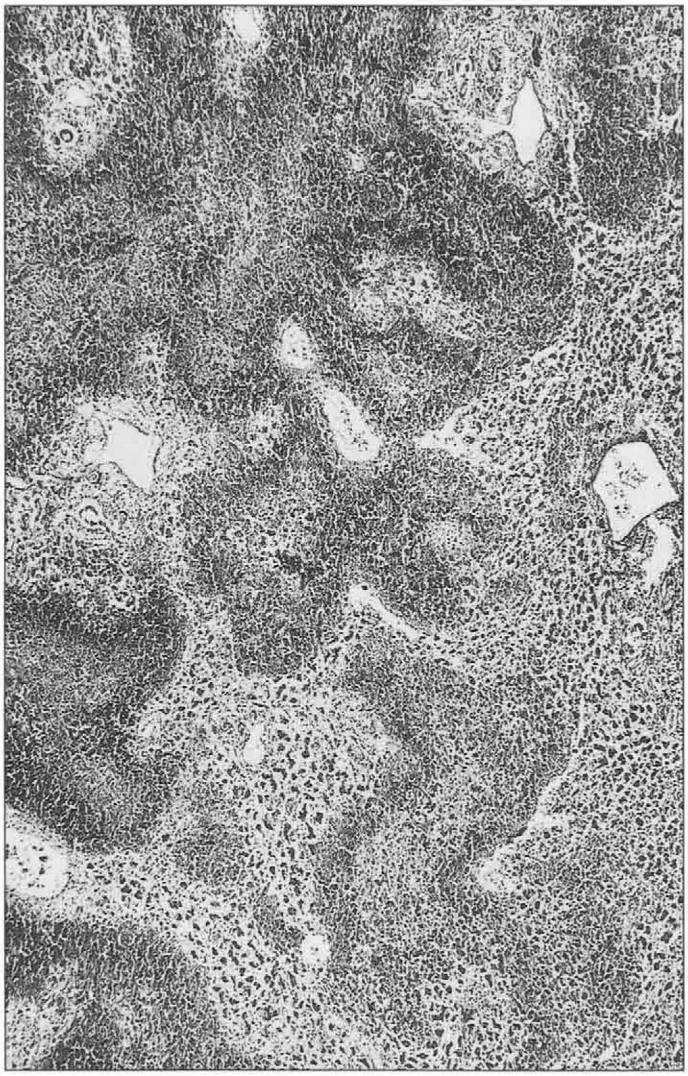

Figure 4.83 *Campylobacter* sp. **necrotizing hepatitis** in an ovine fetus.

to see the characteristic darting motility. Discrimination of the species may be made by culture or application of specific fluorescent antibody techniques.

Flexispira rappini infections

Flexispira rappini is a highly motile anaerobic rod-shaped bacterium with multiple flagella at both of its tapered ends. Although *F. rappini* is the generally accepted name, it has not been firmly classified. The organism is closely related to organisms in the genus *Helicobacter* but is distinguished from them by its unusual spiral grooves visible on electron microscopic examination. Comparable organisms are frequently found in feces of dogs and pigs, and in the stomachs and intestines of a variety of other species.

Flexispira rappini infections in pregnant ewes result in fetal mummification, abortion, and the birth of infected lambs, born weak. It is not considered to be the cause of epizootics of abortion and, as the lesions closely resemble those occurring in abortion due to *Campylobacter* sp. (which does cause epizootics), it is important that it be differentiated.

Naturally or experimentally infected ewes usually abort in the last trimester of pregnancy. The fetus is usually well preserved; however, if it is retained in the uterus, it decomposes rapidly, and the liver may be liquefied. An infected lamb may be born alive, and occasionally only one lamb of a twin may be affected.

Gross and microscopic lesions may be completely absent but, when present, are in the placenta and liver. In the placenta, they consist of a light covering of brown-to-gray exudates on the chorionic surface. In the abdomen, there may be a fibrinous peritonitis, with a thin, loosely attached layer covering the liver. The liver may be congested and enlarged or tan and soft. Multifocal to coalescing pale, brown-to-gray, clearly demarcated, irregularly shaped areas (0.5 cem to several centimetres across) are often visible on the surface and extend into the parenchyma. In both the placenta and liver, lesions not visible grossly may be obvious on microscopic examination. In the placenta, foci of necrosis with accumulations of neutrophils and mononuclear cells may be present on chorionic epithelium. There is heavy infiltration of neutrophils and macrophages in the villus stroma, and severe neutrophil-rich vasculitis may be present in the placental vessels. Capillaries in the villus stroma may be distended with organisms. In the liver, there are multiple, sometimes connecting, foci of necrotic hepatocytes infiltrated by large numbers of degenerating neutrophils, macrophages, and lymphocytes. Hepatocytes in surrounding areas are dissociated.

The condition should be suspected when these lesions are present and *Campylobacter* cannot be isolated. The organism can be seen on dark-field or phase-microscopic examination of a drop of stomach content. It stains weakly gram-negative and is more easily visualized using Giemsa or crystal violet. Special conditions are needed for culture. The organism also produces abortion in guinea pigs.

Listeriosis

Infections by *Listeria monocytogenes* occur worldwide and in a variety of animals, including humans. In ruminants, infections are traditionally associated with cerebral localization and *encephalitis* (for general discussion of the diseases associated with this organism, see Vol. 1, Nervous system). However, *localization also occurs in the pregnant uterus and abortion or stillbirth is then the common sign.* The syndromes of encephalitis and abortion may occur together in a herd or flock, but, rather surprisingly, this is the exception. More commonly one or the other syndrome occurs exclusively. *L. monocytogenes* varies greatly antigenically – serovars 1 and 4b are commonly isolated from cattle, and serovars 4b and 5 from sheep. Serovar 5 (*L. ivanovii*) seems particularly pathogenic for sheep. *L. ivanovii* as a cause of abortion in sheep and cattle occurs less frequently than *L. monocytogenes* and rarely causes other conditions.

L. monocytogenes is shed in the feces of normal carriers and clinically affected animals alike, and has been reported to survive in some soils for as long as 2 years. It is most often *spread by ingestion* of food or water contaminated by feces, urine, placenta, or vaginal discharges from aborting animals. Infection by the oral route, and others, has been shown experimentally to produce abortion. *Silage* is often the source of the organism in severe outbreaks of the infection. The aerobic environment just beneath the surface of a silage bale provides conditions for productive growth of the bacteria. *L. monocytogenes* can multiply in poorly preserved silage with a high pH (6–7.8) but dies at a pH lower than 5.5.

The gravid uterus is highly susceptible to infection, and abortion is experimentally induced by the intravenous injection of pregnant ewes rather than by ingestion. Fetal infection is considered to be by hematogenous spread from the placenta with an incubation period of about 5–12 days. Abortions in both cattle and sheep due to *Listeria* occur during the last trimester of pregnancy. The percentage of pregnant animals that abort within any group is variable; usually the abortions produced are sporadic, but sometimes 50% of pregnant animals may abort. If uterine infection develops during the early part of the last trimester, the organism quickly invades the placenta, and the fetus dies as a result of septicemia. The dead fetus is expelled in approximately 5 days; by this time autolytic changes mask minor gross lesions produced by the organism and all organs teem with bacteria, which continue to multiply after death of the fetus. Abortions at this stage are not usually accompanied by severe systemic disease in the dam. The placenta is typically retained as a result of a mild metritis, but the organisms and associated inflammation are quickly cleared from the nonpregnant uterus.

If the fetus is near term when the infection develops, abnormal parturition is instituted in which dystocia is the rule, severe metritis and septicemia being the most common complications. Lesions in the fetuses and placentas in this group are less likely to be obscured by autolytic changes. Gross lesions consist of *tiny pinpoint yellow foci in the liver* (Fig. 4.84). Similar foci, but usually only visible microscopically, are present in the lung, myocardium, kidney, adrenal, spleen, and brain. These foci have a central area of necrosis in which the organism can be visualized along with small numbers of degenerating neutrophils and mononuclear cells (Fig. 4.85). If the

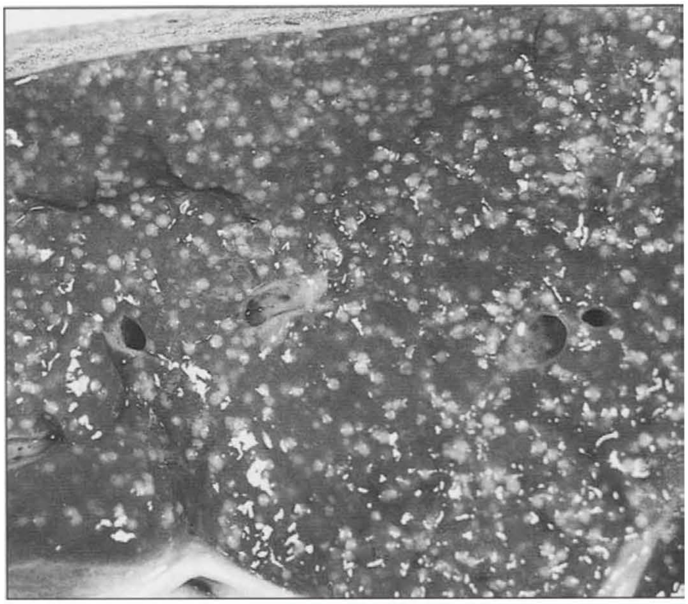

Figure 4.84 Multifocal hepatitis in a fetal calf, caused by *Listeria monocytogenes*.

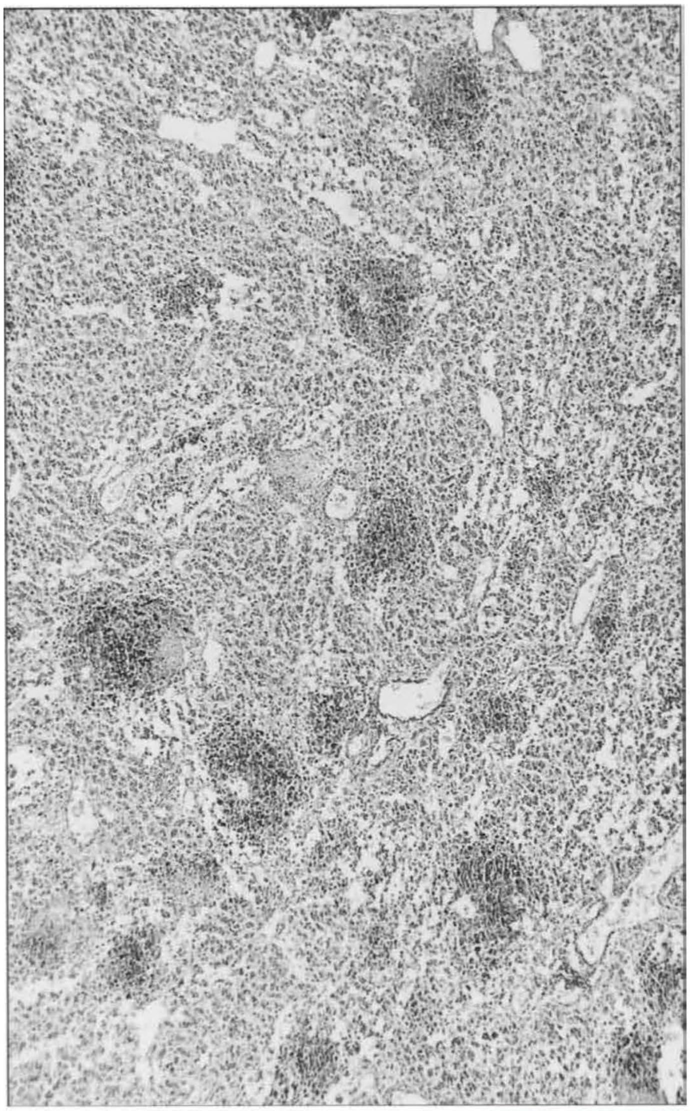

Figure 4.85 Multifocal hepatitis caused by *Listeria monocytogenes* in a bovine fetus.

fetus is near term, there may be severe diffuse nonsuppurative cerebrospinal meningitis in which the organism can also be seen. In the bovine fetus, in spite of marked autolysis, the most dramatic and distinguishing lesion may be in the mucosa of the colon, where *severe necrotizing enteritis* with clusters of colonizing gram-positive bacteria can be seen (Fig. 4.86). The jejunum is autolysed but otherwise normal. Grossly and microscopically, the placental lesion is severe. The necrotic tips of the cotyledonary villi are covered by purulent exudate in which many bacteria are present. There is also focal-to-diffuse red-to-brown *exudative intercotyledonary placentitis*.

Recovery of the organism is sometimes difficult and is probably associated with the advanced autolysis or contamination of some samples. These difficulties can frequently be overcome by refrigerating the specimen (4°C) and reculturing after a period of storage using enriched or selective media.

Clinically affected animals respond well to antibiotic therapy; however, pregnant animals may still abort following recovery.

Leptospira infections causing abortion in cattle

Leptospirosis is a zoonotic disease, widespread throughout the world, and is an important cause of abortion and infertility in cattle. Most often, leptospirosis in cattle is caused by serotypes of the species *interrogans*, specifically, ***Leptospira interrogans*, serovars *pomona* and *hardjo***. *L. interrogans* serovar *hardjo* is maintained by cattle and is found worldwide. Serovar *hardjo* occurs in two strains, *hardjobovis* and *hardjoprajitno*. Strain *hardjobovis* is the only type isolated in North America. This organism is more or less widely accepted to be *L. borgpetersenii* serovar *hardjo* type *hardjobovis*. *Hardjoprajitno* is a highly virulent type of leptospira and has not been isolated in North America but has mainly been associated with cattle in Europe. Both serotypes *hardjobovis* and *hardjoprajitno* are spread by urine, postabortion discharges, infected placenta, and sexual contact, or by in utero infection to the fetus. Serovar *pomona* is maintained by swine and some other animals and is a common cause of incidental leptospirosis in cattle. Vaccines used in the USA to protect against *L. hardjo* type *hardjobovis* infection only contain *L. hardjo hardjoprajitno*.

Exposure of nonvaccinated dairy cows to *L. hardjo hardjobovis* has been shown to be associated with increased breedings required per conception. Diagnosis may be confirmed using immunologically based tests to reveal and identify the organism and routine testing of fetal cavity fluids for antibody. It has become a relatively common diagnosis (0–40% of bovine fetuses submitted), depending on the geographic location. Infection of cattle by either *L. hardjo* or *L. pomona* results in bacteremia followed by damage in various parenchymal organs (especially in the young) and eventually excretion of organisms in milk and urine. Antibody titers develop by 4–6 weeks and may stay up for a year or more. Leptospires may then localize in the proximal renal tubules. Persistence and intensity vary with the organism and the host. *L. hardjo* excretion in urine is usually high for 4–6 weeks but may persist at a lower intensity for 6–12 months or life. Cessation is usually associated with a marked increase in urinary antileptospiral IgG and IgA antibodies. *L. hardjo* may localize in the uterine tube and descend into the uterus and placenta during pregnancy. Systemic infection may produce a febrile response and "flaccid agalactia" with the udder secretion becoming scant, yellow, and thick. The organism may also localize in the placenta and, in some animals, produces fetal disease and abortion.

Most of the abortions due to Leptospira occur in the last trimester of pregnancy and often follow acute infection of the dam by 1–6 weeks (*pomona*) or 4–12 weeks (*hardjo*). *L. autumnalis* usually causes abortion in the second trimester. *L. hardjo* may cause early embryonic death. Fetal infection is not invariably fatal, and weak calves may be born with a substantial antibody titer. *Fetuses that die in utero because of Leptospira infection are usually expelled in an autolysed state.* Abortion rates with *L. pomona* may be as high as 50%, whereas with *L. hardjo* they are generally around 3–10%, and infertility is a common observation in infected herds.

Gross and histologic lesions in the fetus and placenta are nonspecific; however, *the presence of Leptospira-like organisms in trophoblast cells, nonsuppurative meningitis, and nephritis warrants further testing.*

The placenta may be edematous, but inflammatory changes are modest in spite of the fact that there may be clumps of leptospires in the chorionic epithelium. The fetus is often autolysed, and calves in which leptospiral antigen is detected in the placenta weigh 6–10 kg less than calves with no antigen in the placenta. Histologically, multifocal necrotizing tubular necrosis or interstitial inflammatory infiltrates, usually with plasma cells, can be found in the kidneys of some of the fetuses. Occasionally, the fetus will have nonsuppurative meningitis (Fig. 4.87).

The organism may be demonstrated in smears of homogenates of fetal kidney, lung, liver, and placenta, or in fetal aqueous humor by the indirect fluorescent antibody test, or by culture. The organism can also be demonstrated in sections of fixed fetal kidney by immunohistochemistry, or in frozen sections using the fluorescent antibody technique. In stillborn calves, the adrenal glands, lung, and placenta are the most useful organs to examine for leptospiral antigen. Cultures of fetuses can often be misleading. Calves infected with *Leptospira* have been found to be more likely to be infected by *Arcanobacterium pyogenes* or *Bacillus* spp.; the latter is probably an incidental finding, but more easily demonstrated than the *Leptospira*. Cultures of specimens can be productive but are time-consuming and cumbersome with a long delay before results. Fetuses which die when the infection is generalized may not have formed antibody, but antibody is frequently present in cavity fluids by the time the organism has localized in the fetal kidneys. Cows aborting fetuses infected with *L. hardjo* may have high microscopic agglutination titers, but up to 40% are reported as not having a significant titer, and over half of those may have no detectable titer. Prospective serology on a herd basis has been reported to be of considerable value in sorting out titers resulting from vaccination, and either previous or present infections.

Leptospira infections of the pregnant uterus in swine

Abortion is often the only evidence of leptospiral infection in a swine herd. There may be no relationship between return to estrus and leptospirosis. Several serovars of *Leptospira interrogans* regularly infect swine: *canicola, grippotyphosa, icterohaemorrhagiae, sejroe, pomona,* and *tarassovi*. The latter two serotypes, which are adapted to spread in swine, are most commonly associated with fetal disease and abortion. Serological testing has indicated that infection by serovar *bratislava*, or a closely related serovar, is also widespread; and abortions, stillborn, and weak liveborn piglets may have the organism and antibodies to it. Serovar *bratislava* has also been associated with infertility without abortions. In one report, *Leptospira bratislava* was detected in samples of the uterine tube by means of immunofluorescence. Some of the serum samples from these animals were positive for antibodies, whereas others were negative. In one study, where many animals had a positive titer to *Leptospira*, failure to identify *L. bratislava* by immunofluorescence was believed to be associated with transient infections early in life.

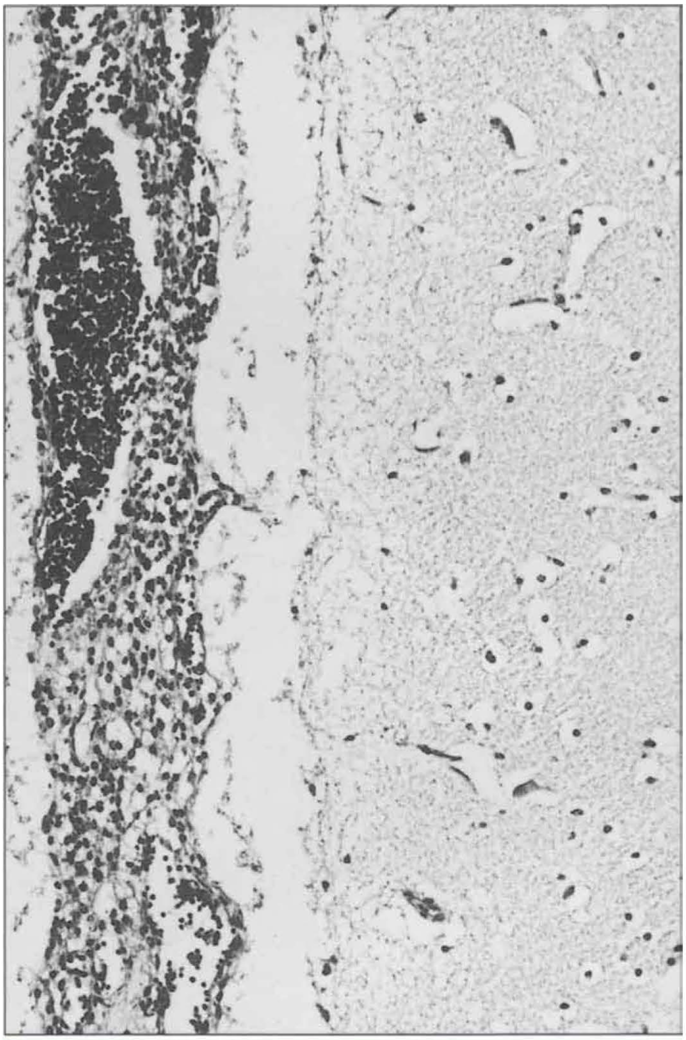

Figure 4.87 Nonsuppurative meningitis caused by *Leptospira* sp. in a bovine fetus.

Leptospires are passed in the urine, and the organisms can enter through mucous membranes or breaks in the skin. Poor management of effluent from piggeries may result in contamination of drinking water, resulting in transmission of the organism to swine and other animals inducing leptospirosis in cattle, sheep, horses, and dogs. Infected swine develop bacteremia before the leptospires localize in the kidneys and uterus, where they may persist and can be shed for months. Systemic signs, if they occur at all, develop during the stage of leptospiremia. It is also during this stage that the organism invades the placenta and infects the fetus. *Most of the abortions due to leptospirosis occur late in gestation, but stillbirths, sometimes with a few partially mummified fetuses, and births of live but weak pigs are also part of the pattern.* Seropositive dams may have a greater risk of having weak newborn piglets and also of having more weak newborn piglets per litter. Infected fetuses often die in utero and undergo autolysis, which obscures any lesions. Some aborted fetuses have elevated immunoglobulin levels.

The placentas of infected pigs may be edematous, but the most severe lesions are seen in those piglets delivered alive, but sick, at or near term. Some of these will be icteric, have patchy hepatic necrosis, fluid, and fibrin in the peritoneal cavity, and inflammatory changes in multiple organs. Focal aggregations of lymphocytes in the renal cortex, medulla and pelvis are characteristic but inconstant. Leptospires can be demonstrated in the kidneys or lungs on section using a silver stain. Special stains are much more useful on tissue sections taken from swine than cattle; however, the fluorescent antibody test for the organism on kidney, lung, and placenta homogenates gives a more definitive answer and allows visualization of the lesion with the antigen. In addition, leptospires may frequently be demonstrated by dark-field microscopy or specific fluorescent antibody test in the urine of the dam up to 2 weeks after abortion and occasionally in fetal cavity fluids from fresh or autolysed fetuses. Leptospires are rarely recognized in fluids from fetuses, which have been frozen, or in fetuses in any condition when aborted because of serovar *bratislava*. Fetal cavity fluids and maternal serum may contain specific antibodies and, along with fluorescent antibody testing of fetal tissues for antigen, makes a practical diagnostic procedure. As in cattle, maternal antibodies may only be useful in diagnosis if examined on a herd basis.

Leptospira infections causing abortion or stillbirth in horses

Until recently, leptospires have not generally been considered to be a major cause of reproductive failure in horses. In Ireland, where tissues from 22 aborted equine fetuses were cultured and examined for leptospires, 9 fetuses were found to contain organisms representing four serogroups: *Australis, Hebdomadis, Icterohemorrhagiae* and *Pomona*. Serovars *bratislava, kennewicki*, and *pomona* are considered to be of major importance in horses, and in one large group of horses tested in Ireland, 89% were found to carry antibody to *bratislava*. The horse is considered to be the maintenance host for *bratislava*.

Foals are usually aborted in the last trimester of pregnancy or stillborn, and gross and microscopic lesions are seldom present. Gross lesions occasionally observed in aborted foals include icterus, yellow mottled liver, mild hepatomegaly, and petechial hemorrhages on mucous membranes. Histopathology may reveal dissociation of hepatocytes, disruption of hepatic cords, multifocal hepatic necrosis, large multinucleated hepatocytes, and renal tubular necrosis. Cerebral perivascular hemorrhage, thrombosis, and severe meningitis with heavy neutrophil and macrophage infiltrates have been observed. In a recent study, leptospires were identified as the cause of abortion in four aborted foals with giant cell hepatitis. For diagnosis, high titers of fetal antibody have been detected in fetal fluid by the microscopic agglutination test and the organism has been identified in impression smears or histologic sections of kidney and placenta by immunofluorescence.

Leptospira infections causing abortion in sheep

A variety of serovars, including *bratislava, ballum*, and *pomona*, will cause abortion and stillbirths in sheep; however, *the major serovar is hardjo*, and with this serovar there seems to be a sheep reservoir that does not include cattle. Sheep seem somewhat resistant to leptospirosis but have a vulnerable period for 2 weeks before lambing and 1 week after. Available evidence suggests that, with different serovars, sheep are usually infected from an environment contaminated by other animals. Feeding newborn lambs with colostrum from *Leptospira*-infected cows is believed to cause death in the lamb. Research has also led to the speculation that leptospirosis is generally less common in sheep than in horses, cattle, and pigs; however, *under conditions of intensive management, leptospirosis can cause severe losses in the last 2 weeks of gestation and early postpartum period.* Losses include abortion, stillbirth, and birth of weak lambs. The grazing lands for sheep are usually arid and therefore do not support leptospires, and the drinking habits of sheep are more fastidious in that they do not normally drink out of puddles.

Ureaplasma diversum infections

Ureaplasma (formerly T-*Mycoplasma*) *is an important cause of reproductive failure in cattle* and ranks second only to *Bovine viral diarrhea virus* as a cause of abortion identified by some laboratories. The true prevalence of abortion due to this organism is obscure, however, as few laboratories have the capability to grow the organism. *U. diversum* is a bacterium in the family Mycoplasmataceae. The organism is frequently present on the mucous membranes of the nasal passages, vulva, and vagina of the cow, the sheath of bulls, and in semen and embryo transfer fluids. It remains in these sites in the animal for long periods, and can be found in urine, and vaginal and nasal discharges. It may be transmitted to cows (or bulls) during breeding, and as the organism is preserved by freezing, it remains viable in diluted frozen semen.

Virulent strains of *U. diversum* may produce *vulvitis, embryonic death, abortion, or the birth of dead or weak calves at term*. Epidemics of abortion are rare in chronically infected herds, but may occur where large groups of naive animals are congregated. Abortion usually occurs in the last trimester of gestation, or infection may manifest as premature delivery, with the birth of weak or dead calves near term. The fetal membranes may be retained. On gross examination, *the amnion is frequently the most severely affected portion of the placenta*. It has patchy thickening with fibrosis and, in addition, may have foci of necrosis, hemorrhage, fibrin exudation, mineralization, and areas that are stained with meconium. The chorioallantois may

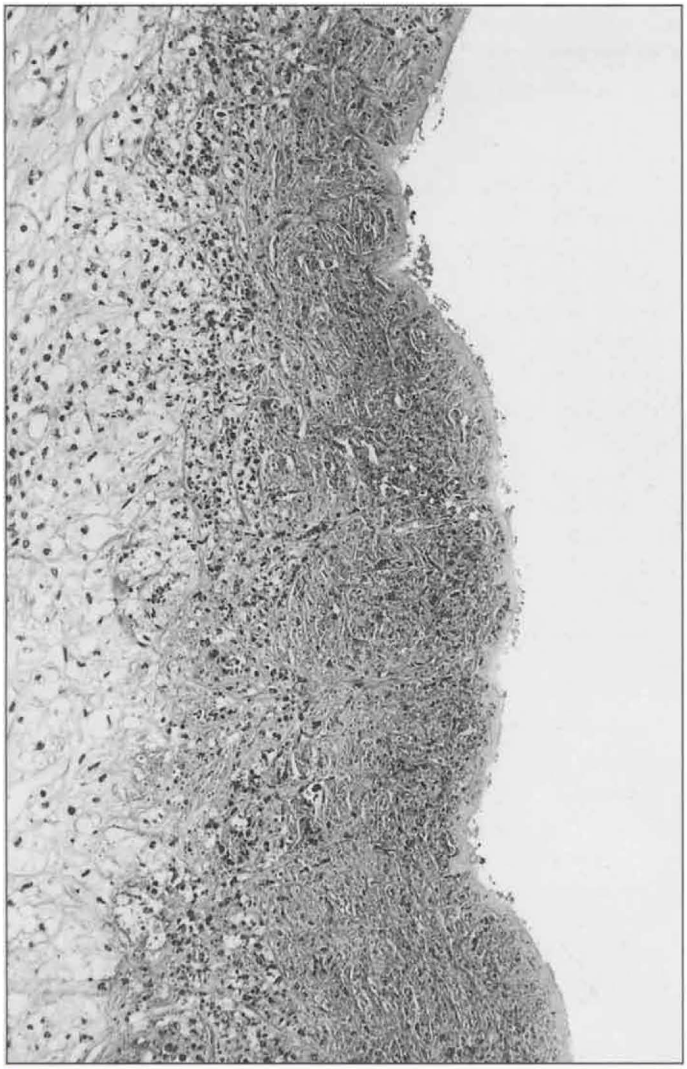

Figure 4.88 Chronic amnionitis due to *Ureaplasma diversum* infection of a bovine fetus.

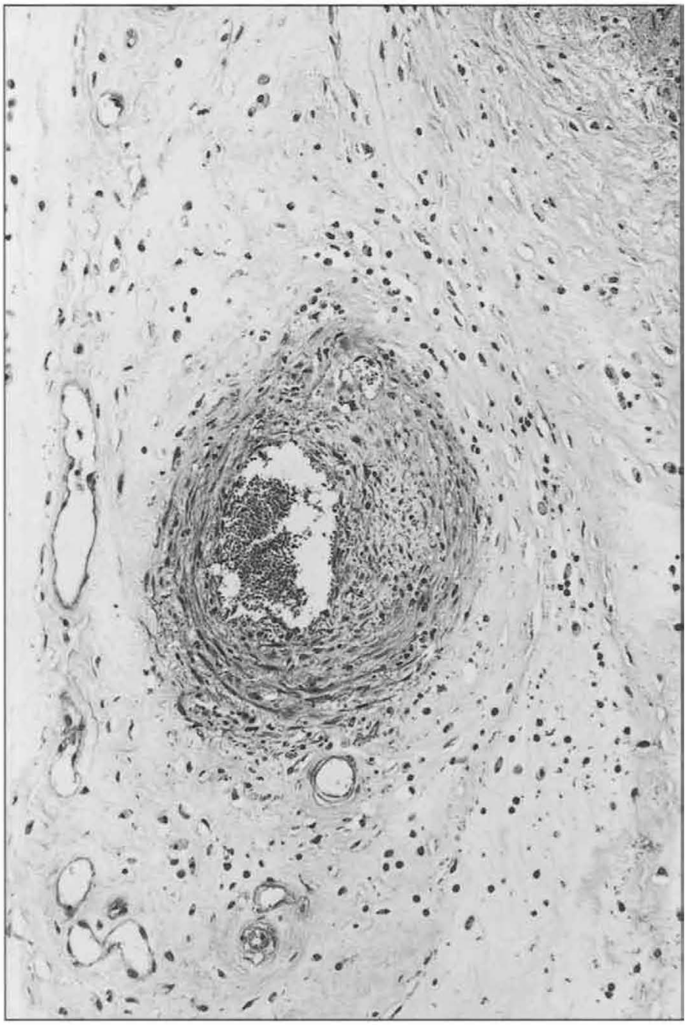

Figure 4.89 Placental vasculitis caused by *Ureaplasma diversum* infection.

be similarly affected, and if so, the lesion is often more severe on the allantoic surface. On histologic examination of the placenta, fibrosis and ongoing interstitial necrosis are extensive. The inflammatory cell component is mainly mononuclear, with macrophages and plasma cells predominating (Fig. 4.88). Mild arteritis is also present (Fig. 4.89).

The fetus is usually well preserved and may be stained with meconium. The lungs are firm and, even if the calf is born alive, are poorly aerated. There is an erosive conjunctivitis with prominent goblet-cell formation of the palpebral conjunctiva. Foci of lymphocytes, including plasma cells, are present in the lamina propria (Fig. 4.90). The lungs have nonsuppurative alveolitis, and periairway lymphocytic mononuclear cell infiltrates may be prominent (Fig. 4.91). *The lesions in the amnion, chorioallantois, and lung are characteristic but not pathognomonic, and require validation by positive culture from placenta, stomach contents, or lung.*

Arcanobacterium pyogenes as a cause of abortion in cattle and sheep

Arcanobacterium (Actinomyces, Corynebacterium) pyogenes is widespread throughout the world as a common cause of pyogenic infection in a variety of domestic animals. The organism is commonly isolated from aborted fetuses and is fairly consistently diagnosed in 1–15% of bovine fetuses submitted. It also causes abortion in sheep, but this is considered less frequent. *It is believed to be a primary pathogen in the cause of abortion.*

The organism is a common contaminant on the mucous membranes, and is found in the tonsils and vagina of healthy cattle. As to the pathogenesis of abortion, it is suspected the organism may penetrate the bloodstream from a mucosal surface, resulting in transient bacteremia, which, in a pregnant animal, results in placental localization and abortion. *Abortion is usually a single event in a herd or flock but is*

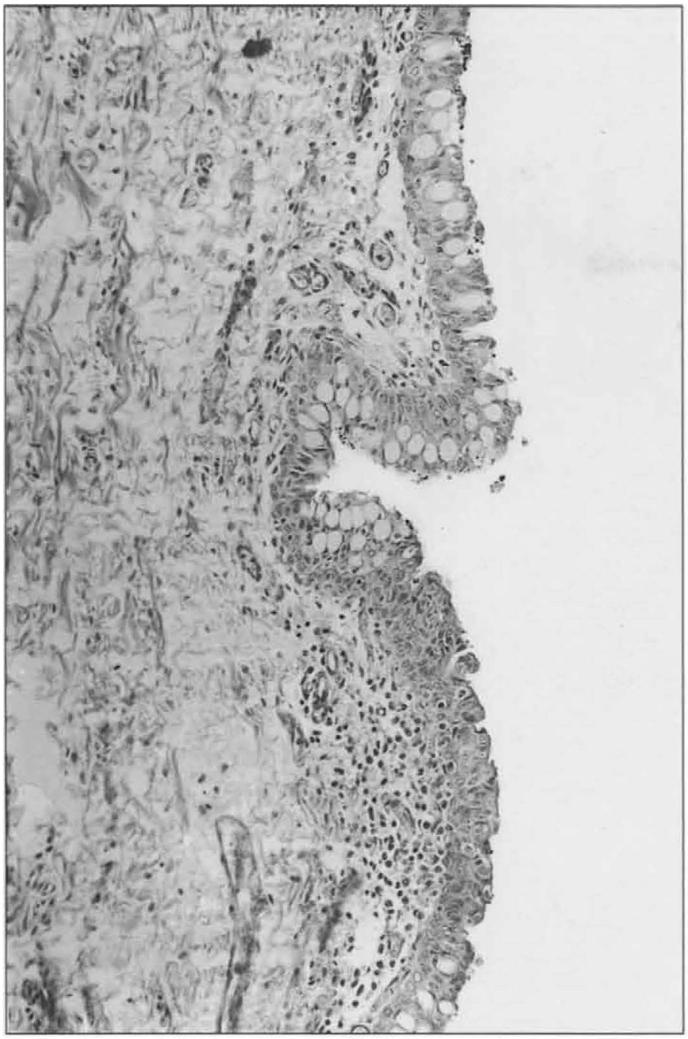

Figure 4.90 Conjunctivitis, with goblet-cell metaplasia, caused by *Ureaplasma diversum* infection of a bovine fetus.

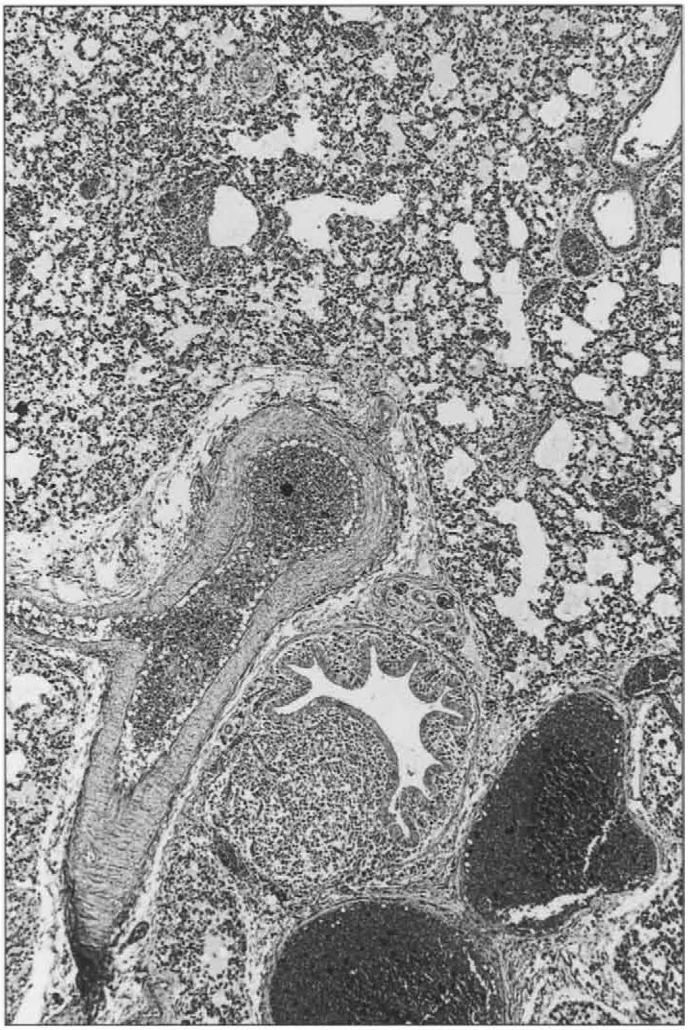

Figure 4.91 Nonsuppurative **alveolitis** and periairway lymphocyte accumulation in reaction to *Ureaplasma diversum* infection of a bovine fetus.

occasionally multiple. Abortion may occur at any stage of gestation but is usually in the last trimester. Dams may be ill following abortion, and some die with suppurative endometritis, arthritis, or mastitis.

The fetus may be severely autolysed or well preserved, and *gross lesions are visible in the placenta, trachea, and lung.* The placenta is often retained and when submitted may be heavily contaminated. Gross examination of portions submitted reveal marked autolysis and suppurative placentitis with yellow-to-brown exudate over swollen edematous cotyledons (Fig. 4.92). In some fetuses, a hemorrhagic cast is present in the trachea (Fig. 4.93). On gross examination of the lung, it is dark red and swollen with minute yellow foci visible on the surface.

On microscopic examination of the placenta and fetus, lesions may be modest (with large numbers of bacteria but no inflammatory cells in placenta and lung) or excessive (with a severe necrotizing, suppurative process in the placenta and acute fibrinous bronchopneumonia in the lung). In addition, bacteria may colonize in vessels, on the skin surface, and on the conjunctiva with destruction of the epithelium.

The **diagnosis** *may be made on seeing the typical lesions and isolating the organism, preferably from the placenta, lung, and stomach contents.* In the absence of lesions, the diagnosis can be made with less confidence by culture only. It has been suggested that the young fetus may be unable to respond to the organism.

Salmonella as a cause of abortion in sheep and cattle

The bacterium *Salmonella* is in the family Enterobacteriaceae. It is a facultative anaerobe, a gram-negative rod, and usually motile. There are over 1300 serotypes in the genus *Salmonella.* Some of these are auxotrophic and have an affinity for just one host, while others are ubiquitous and found in many animals. *S. typhimurium* is ubiquitous, whereas *S. abortus ovis* is most prevalent in sheep and therefore considered auxotrophic. Many of the serotypes causing abortion in livestock are ubiquitous. Salmonellosis is of worldwide concern as a human disease and causes major losses in calves. It is also an important cause of abortion in both cattle and sheep and, in some situations, in mares.

Clinically normal hosts may carry *Salmonella.* It is carried by many mammals and birds, including cattle, sheep, pigs, horses, mice, rats, various birds, including seagulls, and is excreted in the saliva, milk, feces, and urine and in the fluids discharged when animals abort. Animals may become infected through their feed, water, bedding, or the equipment used in feeding, handling, and cleaning. *Abortions are often precipitated by a stressful event such as transport, change in diet, or feeding spoiled feed.* It is not completely defined how these

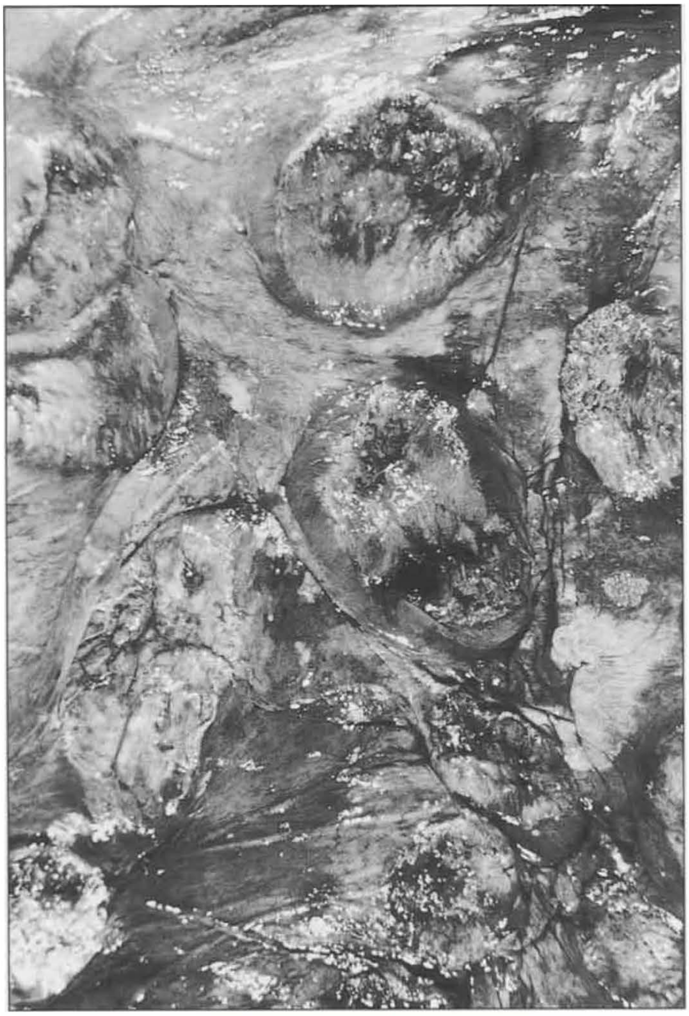

Figure 4.92 Suppurative placentitis caused by *Arcanobacterium pyogenes* infection of a bovine fetus.

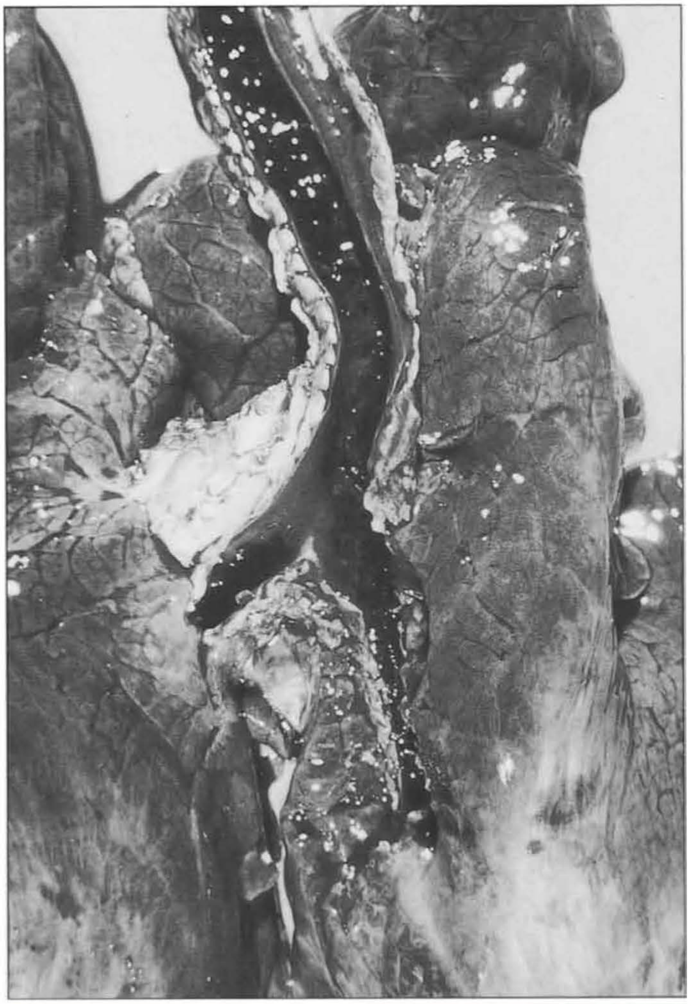

Figure 4.93 Hemorrhagic tracheal cast in *Arcanobacterium pyogenes* abortion of a bovine fetus.

events precipitate increased multiplication of the organism, but it may partly be due to disturbance of the normal intestinal flora. While specific nutrients in the placenta which enhance the growth of *Salmonella* have not been demonstrated, in vivo experiments have shown marked growth enhancement of *Salmonella* following inoculation of whole placental extracts into mice.

The organism may stay in a herd for several years, and *abortions may be sporadic or epizootic, usually occurring in late gestation.* Abortion can occur without illness in the dam or may follow within a week of clinical signs. Cattle may suffer with a variety of clinical manifestations, and in one report, the main manifestations exhibited by *S. dublin* infection varied from pneumonia, to abortion and enteritis, to polyarthritis, in successive years. Signs of enteritis and abortion appear to be commonly associated. Sheep may have a mild upset with fever and anorexia shortly before aborting.

The following *pathogenesis* of placental infection has been proposed. The organism first localizes in the intestine of the dam and this is followed by a brief bacteremia with localization in the lymph nodes, spleen, and lung. After a further period of growth, a second bacteremia occurs in which the placentome becomes infected. Excessive growth of the organism leads to almost complete destruction of the fetal villi, which is followed by abortion and may occur without invasion of the fetus. If *S. dublin* infection occurs within a month of term, the calf may be born alive, carrying the organism.

Following abortion, the placenta is often retained and the fetus is usually autolysed. On gross examination, the chorioallantois is found to be thickened with amber fibrin-containing fluid, the chorionic surface is diffusely gray to red, and there is yellow exudate on the variably tan and red cotyledons. Portions of the caruncle may remain adherent to the cotyledon. Histologically, there is mineralization of individual trophoblast cells, interstitium of the villi, and chorioallantoic arcade. When the chorion is severely affected, mineralization may also be extensive on the allantoic surface. Accompanying the mineral, exuberant bacterial growth expands the villi (Fig. 4.94). In some villi, a heavy infiltrate of neutrophils is present and, if the caruncle remains attached to the cotyledon, there is a clear line of demarcation between the affected villus within the maternal crypt and the near-normal maternal septum. Dilated capillaries, immediately under the sloughed trophoblast cells in the arcade zone, are stuffed with bacteria and in cross-section resemble large rounded trophoblast cells filled with bacteria (Fig. 4.95). In spite of the severe placentitis, there

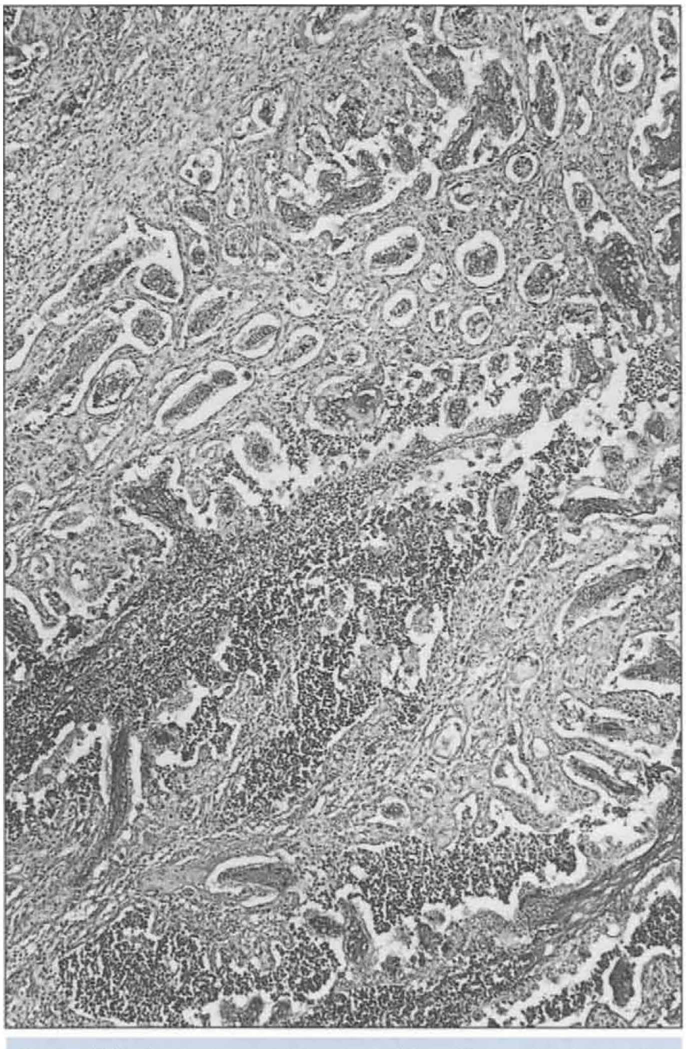

Figure 4.94 Acute suppurative placentitis with complete destruction of villi in the crypt region of a placentome in *Salmonella* abortion in a cow; adjacent caruncle is near normal.

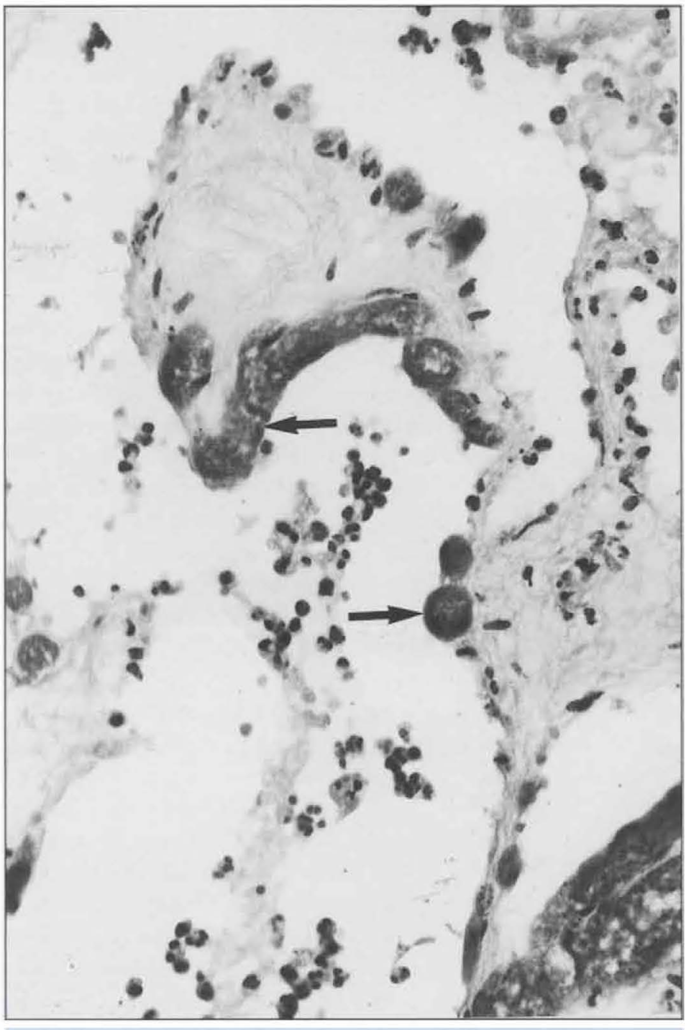

Figure 4.95 Chorionic arcade region, with absence of trophoblast cells in ***Salmonella* abortion** in a cow. Bacteria fill vessels (arrows).

may be no lesions in the lung; however, when present, lesions consist of a moderate to light accumulation of neutrophils in bronchi and bacteria may be seen colonizing airway epithelium. In the liver, there can be multifocal suppurative hepatitis.

Diagnosis is based on recovering the organism from placenta and stomach content. Tissues in the fetus are sometimes negative on culture in spite of marked placentitis. Nearly pure cultures may be obtained from samples of vaginal discharge taken just before abortion. Animals have a remarkable increase in titer following abortion, but this is not a commonly used test needed for diagnosis.

Yersinia pseudotuberculosis as a cause of abortion in cattle, sheep, and goats

Yersinia pseudotuberculosis is a gram-negative coccobacillus in the family Enterobacteriaceae. The DNA of *Y. pestis*, the cause of human plague, and *Y. pseudotuberculosis* are at least 90% interrelated. Six serogroups of *Y. pseudotuberculosis* are recognized based on immunoreactivity of the O antigens. *Y. pseudotuberculosis* causes ileitis, lymphadenitis, and abscessation in humans, and infects a wide variety of domestic, laboratory, and native animals and birds throughout the world. The organism is frequently isolated from the feces of normal cattle, and from abortions in sheep, goats, and cattle. In sheep the organism also causes abdominal abscessation and inflammation in the testis and epididymis.

The *pathogenesis* of abortion probably follows invasion of the intestinal epithelium, transient bacteremia, and localization in the maternal caruncle, followed by passage to the chorioallantois and fetus. It is revealing that in the description of the experimental production of disease in sheep that follows, uterine, and specifically caruncular, disease was present as in naturally occurring abortion. It is possible that nutrients in the caruncle favor localization and growth of *Yersinia* that is followed by villus infarction and invasion of the chorion.

Lesions reported are based on limited observations that are generally similar in aborted fetuses and stillborns from sheep, goats, and cattle. The aborted conceptus is usually well preserved and contains a variety of lesions. Placentitis is largely confined to the cotyledons. Cotyledons are red or tan, thickened and relatively devoid of exudate on the surface. Portions of the caruncle may remain attached. The intercotyledonary region is usually translucent but a frosting of fibrin and some fibrosis may closely surround the affected cotyledons (Fig. 4.96). The thoracic and abdominal cavities contain excess amber fluid with some fibrin. In the fetal liver, there may be pale tan focal areas of necrosis ranging in size from 0.1 to 1 cm. No other gross lesions are observed.

Histologically in the placenta, there is necrosis of villi and moderate infiltration of granulocytes, macrophages, and mononuclear cells in the interstitium of the chorioallantoic arcade. In placental vessels, there is fibrinoid necrosis of the media accompanied by mononuclear cell and neutrophil infiltrates. Lesions in the attached portions of caruncle consist of thrombosis of septal vessels, hemorrhage, and necrosis, with a heavy diffuse infiltration of neutrophils and mononuclear cells. In the lamina propria of the conjunctiva, there are focal infiltrations of mononuclear cells, plasma cells, and a few neutrophils (Fig. 4.97). In the lung, there are a few mononuclear cells in airways. Hepatic lesions consist of focal areas of necrosis infiltrated by granulocytes and mononuclear cells. Similar foci are visible on microscopic examination of myocardium and lymph nodes. Peyer's patches are precociously cellular. The lamina propria and submucosa of the colon are heavily populated by plasma cells and mononuclear cells, and within the lumen, colonies of the organism and scattered inflammatory cells can be seen in the meconium (Fig. 4.98).

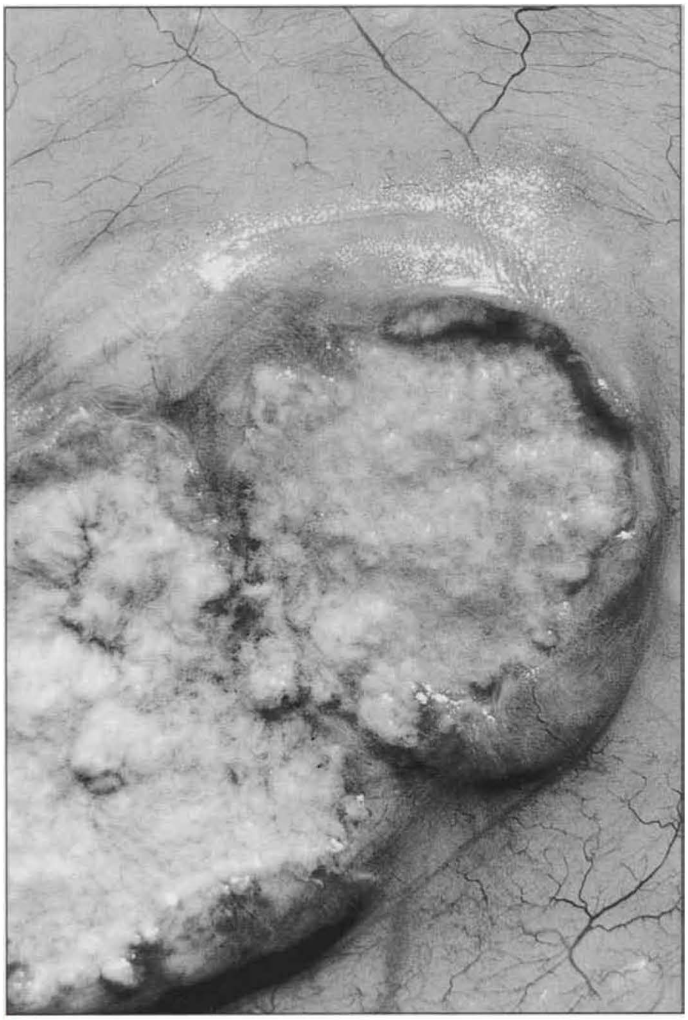

Figure 4.96 Chronic suppurative cotyledonary placentitis and pericotyledonary fibrin in *Yersinia pseudotuberculosis* abortion in a cow.

Extensive lesions in the uterus follow the experimental production of abortion in sheep. They consist of thrombosis of septal vessels, necrosis of septa, and heavy infiltrations of granulocytes in caruncles and intercaruncular regions.

Diagnosis *is based on recovery of the organism from placenta, stomach content, or lung, and the lesions described.*

Histophilus somni infections of the pregnant bovine uterus

Histophilus somni (formerly *Haemophilus somnus*) is the only species of the genus *Histophilus*, family Pasteurellaceae, and encompasses bacteria isolated from cattle and previously described as *Haemophilus somnus*, as well as ovine isolates formerly referred to as *Histophilus ovis* and *Haemophilus agni*. *H. somni* is a fastidious gram-negative coccobacillus that is considered normal flora of the male and female bovine genital tract. There are marked differences in the ability of different isolates

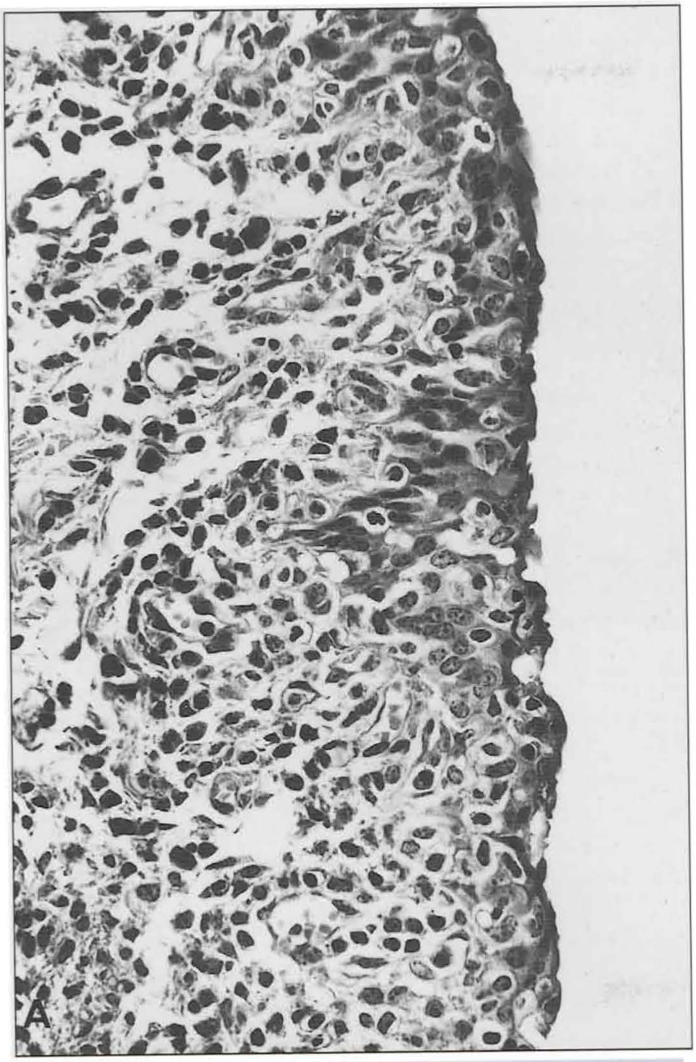

Figure 4.97 Nonsuppurative conjunctivitis in aborted calf with *Yersinia pseudotuberculosis* infection.

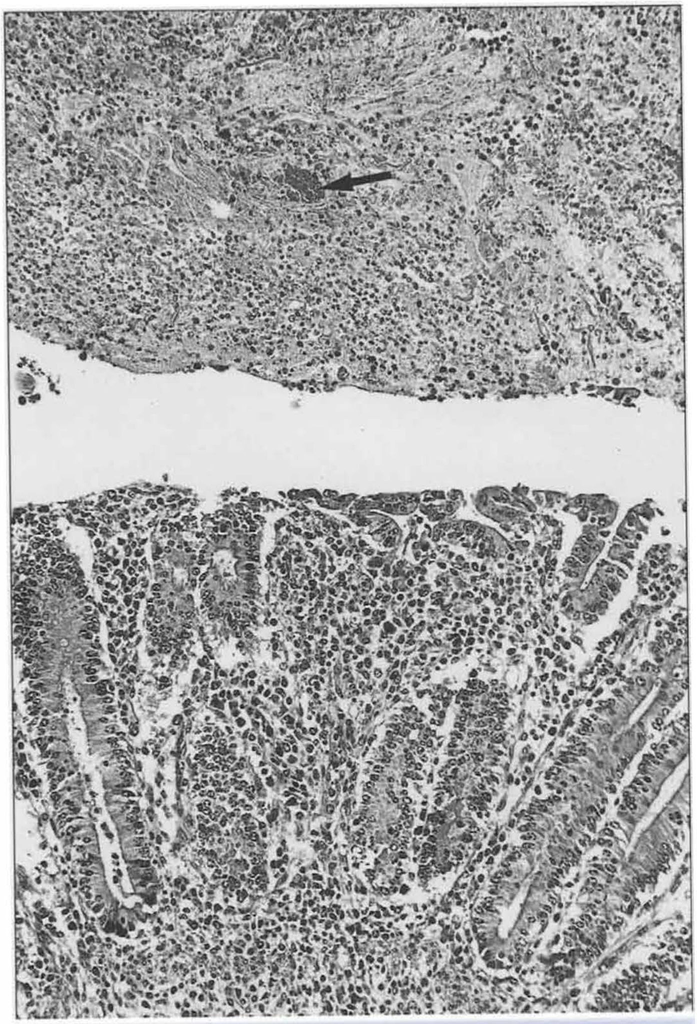

Figure 4.98 Lymphoplasmacytic colitis, with colonies of *Yersinia pseudotuberculosis* in meconium (arrow).

from the reproductive tract to produce central nervous system disease. Preliminary experiments have not shown the reverse to be true.

H. somni is best known for its association with central nervous system disease and pneumonia in cattle, and these are discussed under those sections. *The organism is often associated with vaginitis, infertility, abortion, and occasionally with fatal endometritis.* Usually abortions induced by *H. somni* involve solitary animals; however, occasionally an entire herd will develop reproductive disease, including vaginitis and infertility attributed to this organism. When this occurs, predisposing factors, in the form of malnutrition, concurrent virus infection, or stress, should be considered.

The organism is commonly resident in the vagina of cows (3–76% of animals sampled), and in the prepuce of bulls (more than 75% positive). Natural breeding therefore easily spreads it. Most strains of the organism are sensitive to the antibiotics used in the preparation of frozen semen. Sampling of a naturally infected herd revealed over 50% of calves infected by 7 months of age. The presence of the organism in the vagina does not imply clinical disease.

The *pathogenesis* of abortion has not been clarified. The organism shows some ability to penetrate the cervical area to infect the placenta; however, lesions in the placenta are usually in cotyledons, which suggests a hematogenous route. Bacteremia following a vaginal or respiratory infection is likely. *Death of the fetus after infection is usually rapid, resulting in the abortion of a severely autolysed fetus.*

Lesions in the placenta are primarily confined to the cotyledon and consist of acute nonsuppurative placentitis, which does not appear to penetrate to either the amnion or allantoic surface. On histologic examination, the most distinctive lesion in the placenta consists of severe fibrinoid necrosis and thrombosis of large and small arteries (Fig. 4.99). The cellular infiltrate in vessel walls and adjacent villi is mainly macrophages with some neutrophils. There is sparing of veins and capillaries. Colonies of bacteria are visible next to the trophoblast cells. Lesions in the fetus are usually sparse; however, acute fibrinous bronchopneumonia is occasionally observed. On histology, airways are seen to contain degenerating mononuclear cells, macrophages, but few neutrophils. Bacteria are frequently observed adjacent to the epithelium of alveolar ducts, and swirling (oat-type) macrophages are numerous in these areas. Fibrin often fills lymphatics, distending interlobular septa.

Diagnosis *is based on observing the characteristic lesions in the placenta and lung, and isolation of the organism from the stomach content or placenta.*

Chlamydophila (Chlamydia) infections causing abortions

Chlamydophilae (chlamydiae) are obligate intracellular parasites that multiply in membrane-bound vacuoles in a variety of cells. They have two distinct forms, the reticulate body, which is not infectious, and the elementary body, which is infectious and released from the cytoplasm by a mechanism not fully understood but which involves disruption of the cell. The inclusions, which can be seen on light microscopy, consist of hundreds of gram-negative *Chlamydophila* cells bound by a membrane in a cytoplasmic vacuole. Based on DNA sequence analysis, the family Chlamydiaceae is divided into two genera: *Chlamydophila* and *Chlamydia*. The species of *Chlamydophila* and *Chlamydia* of veterinary interest include the re-designated forms of *Chlamydia psittaci*, namely *Chlamydophila abortus* (former ovine serovar (immunotype) 1), *C. psittaci* (former avian serovar), *C. felis* (feline serovar), *C. caviae* (guinea pig serovar); plus *C. pecorum* (mammals), and *Chlamydia suis* (former porcine serovar of *C. trachomatis*). *C. suis*, *C. pecorum*, and *C. abortus* have all been associated with reproductive

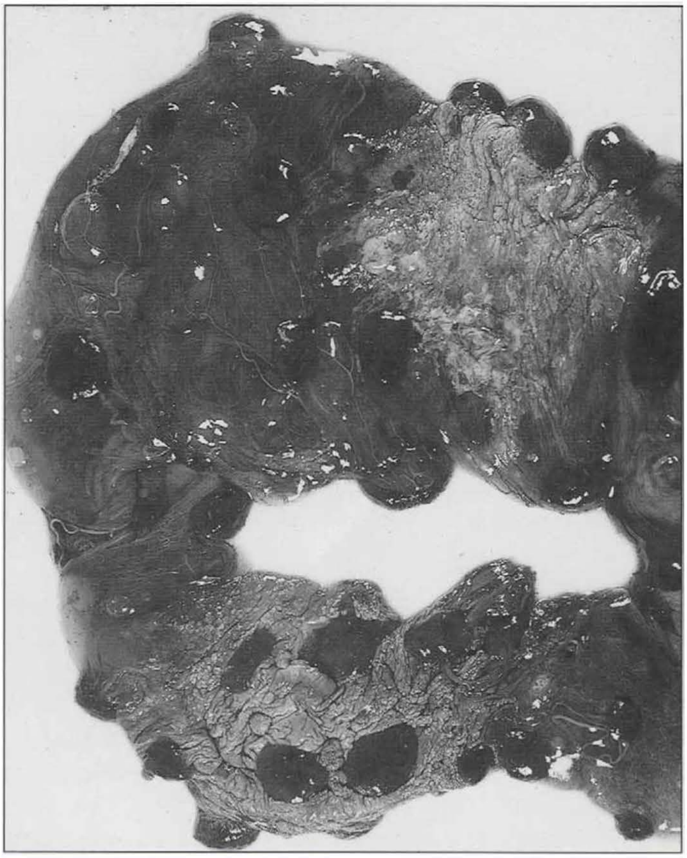

Figure 4.100 **Chlamydial placentitis** in a sheep.

failure and abortion in swine. Chlamydiae have also been associated with abortion in horses. Of significance as human pathogens are *C. psittaci*, *C. pneumoniae*, and *C. trachomatis*.

Chlamydophila abortion in sheep, goats, and cattle

Chlamydophila abortus (C. psittaci) is an important cause of in utero infections in sheep and goats, resulting in abortion, stillbirth, and the birth of weak offspring, and can cause abortion in women in close contact with these aborting ruminants. The disease in sheep has been known as "ovine enzootic abortion," and "enzootic abortion of ewes," but will be referred to here as *Chlamydophila* abortion.

Contamination of foodstuffs with feces or the products of abortion containing the organism transmit the organism orally. On entry into sheep and goats, *C. abortus* may infect the intestine permanently, and from here invade the bloodstream as a chlamydophilemia, and infect the placenta and frequently the fetus in pregnant animals. Naive animals, including newly introduced sheep and females pregnant for the first time, are most vulnerable. *The infection is chronic and abortion usually occurs in the final trimester of pregnancy, or infection may manifest as stillbirths or weak lambs.* Extensive losses (30%) may occur on introduction of the organism to a flock, and yearly rates of 5% are common when it exists in the enzootic form.

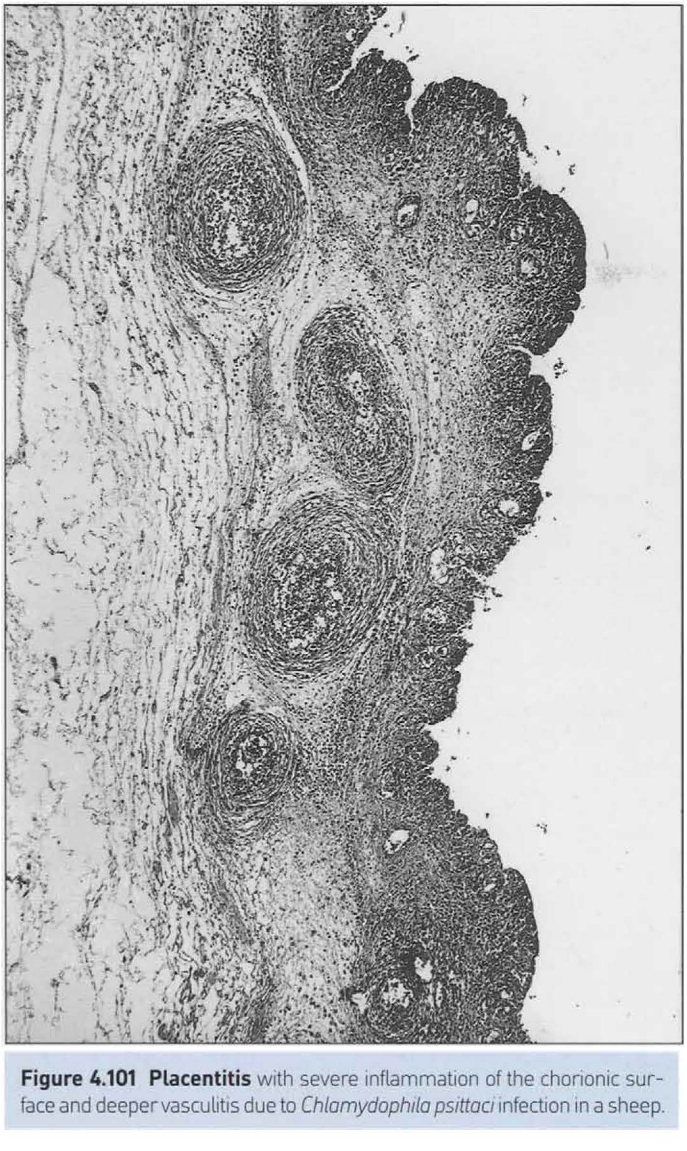

Figure 4.101 Placentitis with severe inflammation of the chorionic surface and deeper vasculitis due to *Chlamydophila psittaci* infection in a sheep.

Retention of fetal membranes may occur in some animals, and aborting females may occasionally be ill. *The placenta resembles that seen in bovine brucellosis* and there is patchy, almost equal involvement of cotyledons and intercotyledonary regions. Affected cotyledons are a dull-clay or dark-red color, firm, and matted with a dirty-red exudate. The intercotyledonary region is red to brown and has irregular patches of edema amidst a dry, leathery thickening of the chorioallantois (Fig. 4.100). These thickenings are often concentrated in ridges, which on histology are seen to consist of medium to large vessels prominent because of *marked vasculitis*. The vasculitis is characterized by fibrinoid necrosis of the media with a moderate to heavy infiltrate of neutrophils and some mononuclear cells (Figs 4.101, 4.102). In the chorion, there is superficial necrosis, and characteristic inclusions can be seen in the cytoplasm of trophoblast cells. Abortion is likely the result of several factors, including tissue destruction by *C. abortus*, vasculitis, and thrombosis, and a fetal inflammatory response. Production of tumor necrosis factor-α by fetal macrophages that express major histocompatibility complex II molecules may be significant in the pathogenesis of abortion.

The fetus is usually well preserved but may have few gross lesions. These consist of scattered hemorrhages in the subcutis, thymus, lymph

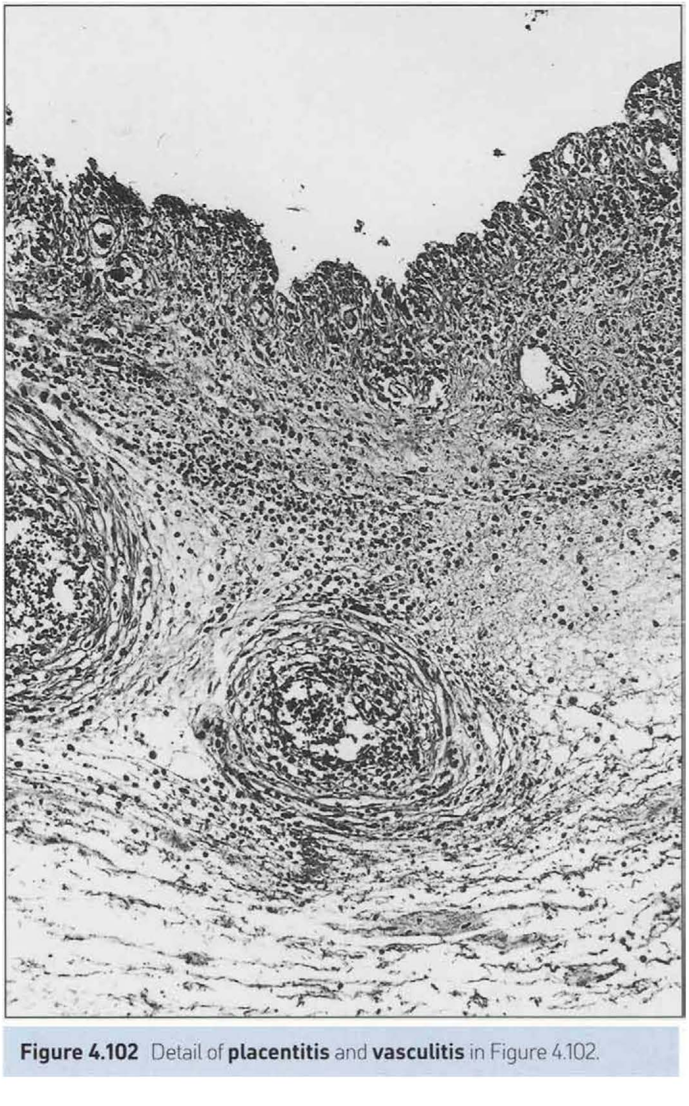

Figure 4.102 Detail of **placentitis** and **vasculitis** in Figure 4.102.

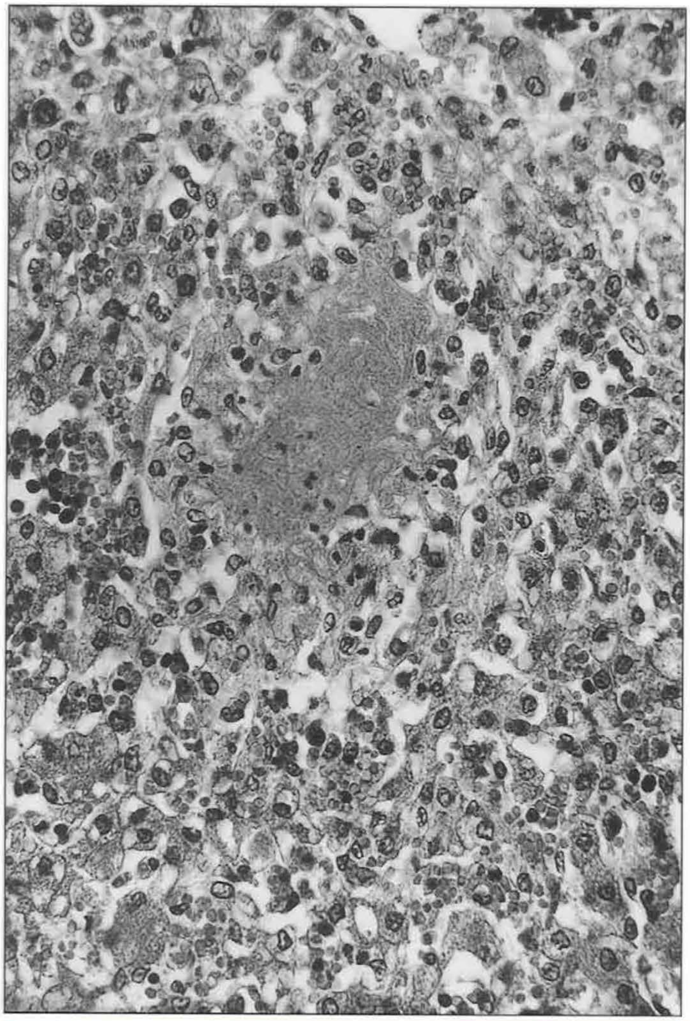

Figure 4.103 Focal coagulative necrosis in liver in *Chlamydophila psittaci* abortion.

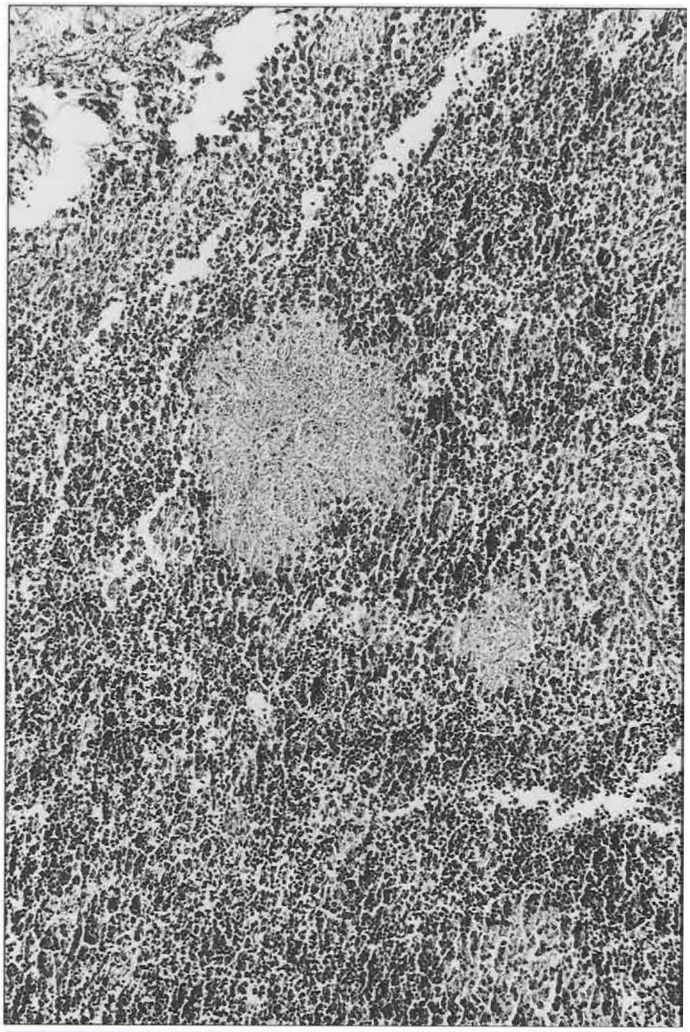

Figure 4.104 Focal coagulative necrosis in spleen of a sheep.

nodes, and muscles. The liver is sometimes swollen and has pinpoint yellow foci on the surface. Histologic lesions in the fetus are modest but characteristic. *There are focal areas of coagulative necrosis in the liver and spleen.* These foci consist of as few as five cells, stain pale pink, and are variably surrounded by a scant infiltrate of mononuclear cells (Figs 4.103, 4.104). Throughout the liver and concentrated in portal areas there is an increase in mononuclear cells. In the lung, alveolar septa are thickened by mononuclear cell infiltrates. Mild meningoencephalitis with vasculitis and hemorrhage has also been reported.

Cattle do carry *Chlamydophila* in the intestine, as do sheep, and the organism in the intestine can produce abortion. Abortions in cattle are usually sporadic, occurring throughout the year with occasional outbreaks in isolated herds. Fetal lesions are similar to those in lambs. *Waddlia chondrophila*, another member of the order *Chlamydiales*, is also responsible for abortion in cattle.

In order to establish *Chlamydophila* as the cause of an abortion in cattle or sheep, the organism should be demonstrated in a smear (preferably of placenta) stained by a modified Ziehl–Neelsen, Gimenez, or Giemsa method. The organism can also be demonstrated in sections from the diseased placenta using a specific fluorescence antibody test or immunohistochemistry. The presence of specific antibody in the fetus is confirmative, but antibody is not always present. Demonstration of antibody in the dam is of little use as a large proportion of cattle and sheep have been exposed and test positive. Specific monoclonals are becoming available to detect antigens of known pathogenic strains of *Chlamydophila*. Eluates, prepared from specimens containing the organism, can be grown on appropriate cell lines on coverslips, fixed, stained, and examined within 3 days. This method is very effective in detecting *Chlamydophila*.

Abortion in sheep, goats, and cattle caused by *Coxiella burnetii*

Coxiella burnetii is in the family Rickettsiaceae and is the only member of the genus *Coxiella*. The organism is well known as the cause of Q (query) fever in humans. It is an obligate intracytoplasmic parasite. *Dairy cows, goats, and sheep are the common reservoirs of the organism,* and some forms of wildlife may also carry it. They are probably not the source of the organism but acquire it from domestic animals. Human and domestic animal infection occurs when contaminated dust is inhaled; however, massive contamination of a paddock or pasture facilitates oral transmission. Infection apparently persists indefinitely in sheep and cattle, and organisms are shed at parturition and in the milk and feces. Abortion usually follows initial exposure and may be unusual in endemically infected flocks.

Abortion tends to occur late in the gestation period, and weak lambs and kids may be born during an outbreak. The aborted fetus may be well preserved or autolysed. *Gross lesions are confined to the placenta, which is thickened and leathery*, with multifocal to confluent areas of mineralization. The exudate is copious, off-white, and most obvious in the intercotyledonary region (Fig. 4.105). If the cotyledon is involved, the early lesion appears as a white outer ring with flecks of white scattered in the central region. Histologically, there is acute diffuse suppurative placentitis with heavy neutrophil infiltration and extensive necrosis of cotyledonary villi and intercotyledonary epithelium (Fig. 4.106A). In contrast, the cellular infiltrate in the interstitium of the chorioallantoic arcade is largely mononuclear, with a predominance of plasma cells. The lesion, which on gross section appears to be largely confined to the intercotyledonary region, is frequently found on histology to be also extensive in the cotyledons, especially at the periphery. The vasculitis that develops with *Chlamydophila* infections is not usually a feature of placentitis due to *Coxiella*. *Smears of the placental exudate contain large numbers of organisms*, which can be stained by the modified Ziehl–Neelsen or Macchiavello's stain. Invasion of the cells of the chorion by the organism produces microcolonies, which distend the cytoplasm of the infected cells (Fig. 4.106B). These microcolonies can be seen in conventionally stained sections, but must be distinguished from similar colonies that *Chlamydophila* organisms form. With hematoxylin and eosin stains, *Chlamydophila* inclusions tend to stain poorly and appear more homogeneous, whereas with *Coxiella*, cells containing the organism frequently have a characteristic foamy appearance with multiple unstained vacuoles within a pale blue cytoplasm. The nucleus, if visible, is usually pushed against the cell wall and assumes a crescent shape.

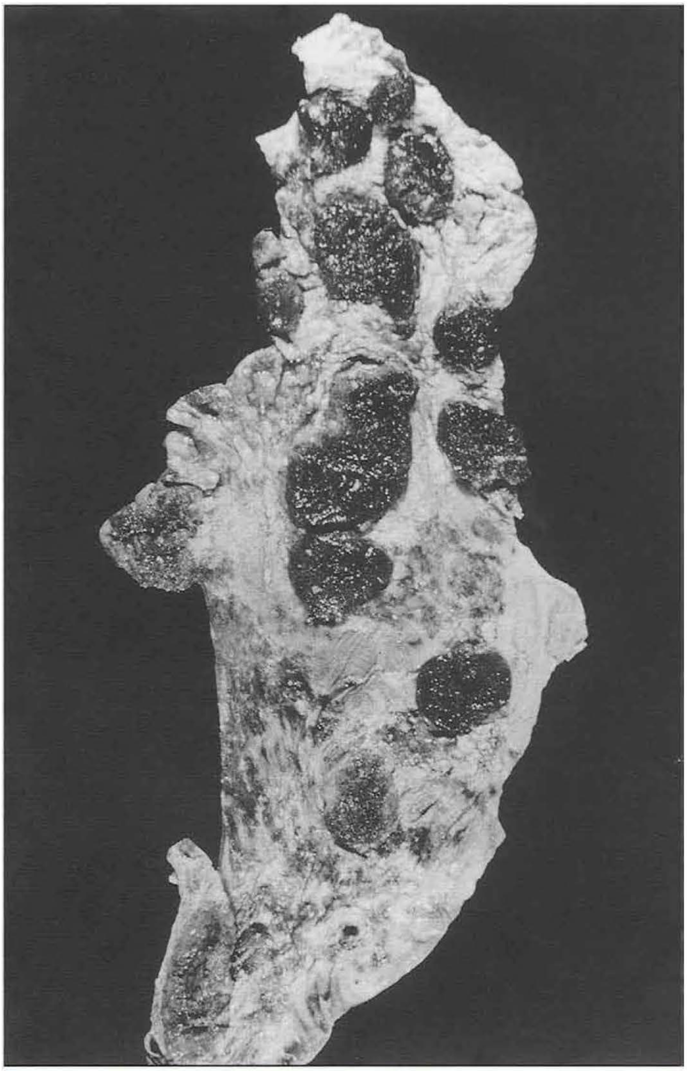

Figure 4.105 Suppurative intercotyledonitis in *Coxiella burnetii* abortion in a goat.

The histologic lesions in affected fetuses are usually modest. Granulomatous hepatitis and nonsuppurative pneumonia with occasional focal lymphoid accumulations around bronchioles have been described. A few lymphocytes and macrophages may infiltrate the renal medulla and surround the portal vessels of the liver.

Bovine fetuses may also be aborted due to *Coxiella* infections. The lesion in the placenta is characteristic and similar to that observed in sheep and goats. Care must be taken in attributing the simple presence of *Coxiella* as sufficient evidence for the cause of abortion. Animals may carry the organism for a prolonged period and, although they appear to abort only once, there may be large numbers of organisms in the placenta in subsequent pregnancies. Assessment of the extent of the placental lesion may be helpful.

Diagnosis is routinely based on the characteristic placental lesions and the appearance of the organism in impression smears stained by a modified acid-fast technique. More definitive methods utilizing direct or indirect fluorescent antibody techniques are available.

Mare reproductive loss syndrome and late-term abortions

A syndrome of abortion reached epidemic proportions in the spring of 2001 and to a lesser extent in 2002. It is of major concern to the equine industry in various states but especially in *Kentucky*. Several hundred late-term fetuses were examined. Most were aborted or stillborn at term or several weeks before term, well preserved, and enclosed within the placenta. There were few or no premonitory signs of illness in the mares. Lesions observed in the fetus included hyphema and little or no inflation in the lungs. Hemorrhages were frequently observed on the chorion, amnion, and amniotic segment of the umbilical cord, pleura, and heart. The surface of the amniotic segment of the cord was dull gray to yellow, roughened, and thickened by stromal edema. On microscopic examination, the amniotic cord had bacteria on the surface and where there was loss of epithelium there were light to heavy infiltrations of neutrophils and macrophages. Similar light infiltrates were seen in the stroma of the allantochorion.

Cultures of the fetus and placenta yielded non-β-hemolytic *Streptococcus* spp. and/or *Actinobacillus* spp. in 50% and 20% of the specimens cultured. Similar bacteria were also cultured from lung, stomach content, and placental membranes. Microscopic lesions included funisitis, amnionitis, pneumonia, fetal bacteremia, and sometimes chorionitis. Further investigations supported unusually warm weather and rate of change from cool to warm as major factors, which correlated with increased bacterial growth and *eastern tent caterpillar (ETC)* development. In a controlled study, investigations involving the feeding of ETC to pigs caused abortion. A similar study in mares revealed that abortion occurred only on feeding of the insect exoskeleton, and that hair remnants resembling ETC setae were embedded in the submucosa of the digestive tract of aborting gilts and of an aborting mare. *A factor in or on the ETC cuticle may be responsible for equine abortions.*

Nocardioform placentitis in mares

This disease, caused by actinomycete bacteria, is primarily found in *central Kentucky,* with a few similar cases reported elsewhere. All ages and breeds of mares are affected. The mare shows no outward signs of illness, except, as with other near-term abortions, premature development of the mammary gland and lactation may occur. Infection is cleared early and rebreeding has not been accompanied by problems. The bacteria involved are *gram-positive branching filamentous organisms,* and include at least three different genera of bacteria: *Crossiella equi, Streptomycin,* and three species of *Amycolatopsis.* No risk factors have been identified, nor has the condition been reproduced.

The lesion in the placenta is somewhat unique in that infection does not seem to start at, nor communicate with, the cervical star. The chorionic surface of the most cranial portion of the body and entrance to the uterine horns is covered with thick brown exudate containing sloughed chorionic cells, neutrophils, and bacteria. The bacteria invade the chorionic epithelium but have not been identified in fetal fluids and organs.

Miscellaneous infections causing abortion in mares

That group of *bacterial infection* in foals producing the syndromes variously known as joint ill, navel ill, foal septicemia, and pyosepticemia neonatorum can also produce abortions and stillbirths. The implications of this are that these diseases of the newborn can be continuations of intrauterine disease. The organisms involved, in approximately the order of frequency, are: β-hemolytic streptococci, *Escherichia coli, Pseudomonas, Staphylococcus aureus, Klebsiella pneumoniae,* and *Actinobacillus equuli.* These organisms may occasionally reach the chorion by way of the bloodstream of the dam, but most ascend through a patent cervix (Fig. 4.107). This produces inflammatory thickening of the placenta adjacent to the internal os of the cervix.

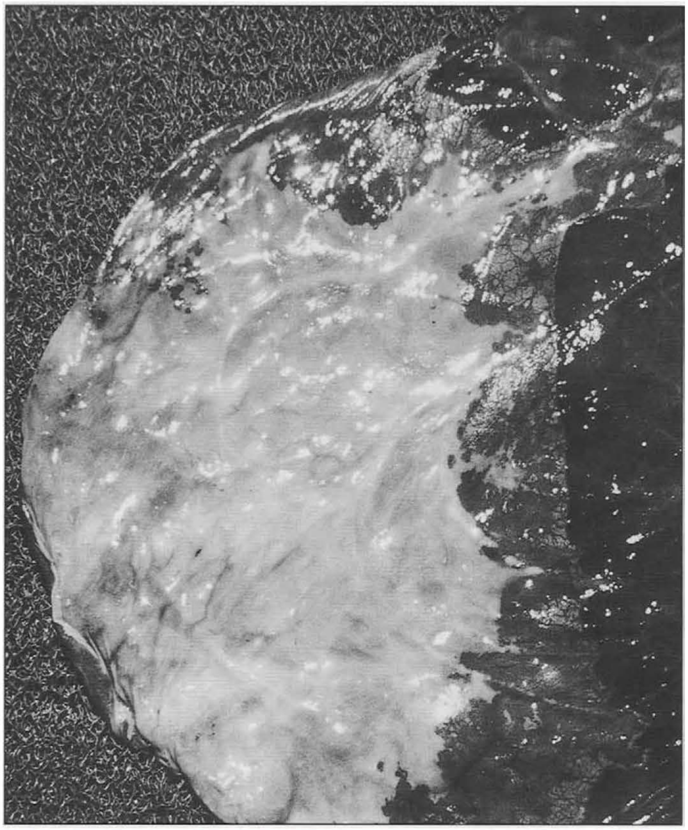

Figure 4.107 Placental thickening following transcervical infection with *Streptococcus* sp. in a mare.

Fungal infections frequently have the same pathogenesis and produce a similar placental lesion with a sticky brown exudate covering the surface of the affected areas of the chorion (Fig. 4.108). *Aspergillus fumigatus* is the most commonly isolated fungus, but *Absidia corymbifera* and other *Aspergillus* species have been recovered.

Actinobacillus equuli is an important cause of neonatal death of foals in most countries. Foals may become infected in utero and be aborted, as discussed above, or they may die of septicemia in the early neonatal period, or they may survive for several days and develop foci of localization in many tissues. It is probable that some of these infections are acquired during or after parturition. Aborted foals and those dying acutely of septicemia do not have distinctive lesions. After a course of 3 or 4 days or more, localization of the infection with miliary microabscessations and polyarthritis develops. The microabscesses, which are embolic in origin, may be found in many organs, and they are readily visible to the naked eye in the renal cortices. The renal abscesses are small, being only 1–3 mm in diameter, and numerous. Histologically, bacterial colonies are obvious in the glomeruli and intertubular capillaries and are enclosed in foci of intense suppuration. The arthritis is fibrinopurulent.

There is little information on the epidemiology and pathogenesis of actinobacillosis. Mares, which are caused to abort by this infection, are not ill, and the organism does not persist for long in the uterus after abortion. However, the same mare may abort successive pregnancies, a fact which suggests that the uterus can be reinfected from some endogenous asymptomatic focus. *A. equuli* can occasionally be found in the intestine and tissues of healthy animals, and also as an

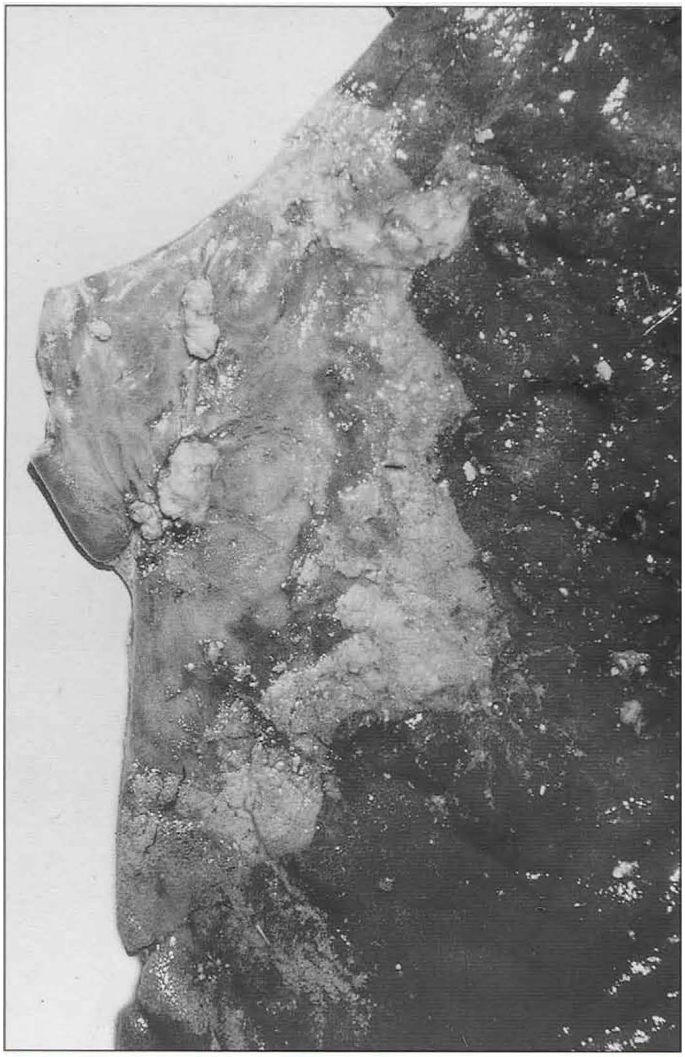

Figure 4.108 Mycotic placentitis following transcervical infection in a mare.

opportunist in pathological tissues such as verminous thromboses. It is, however, seldom of significance in adult animals, although septicemic infections have been observed.

Rhodococcus equi is an important cause of pneumonia and colitis in foals less than 6 months of age, and a rare cause of placentitis and abortion. The fetus may be expelled within the membranes. The cervical star and surrounding region may be red; the lungs are pale and fail to float. *R. equi* may be isolated in pure culture from the placenta, lungs, liver, and stomach content. The lesion in the placenta consists of a perivascular macrophage infiltrate with a few lymphocytes and neutrophils. The macrophages contain numerous gram-positive coccobacilli. Inflammation is most extensive on the allantoic surface. On microscopic examination, there is multifocal hypertrophy and hyperplasia of allantoic epithelial cells, and small numbers of neutrophils and large macrophages are loosely scattered within the amnion. Pulmonary alveoli contain a few granulocytes and many macrophages, some of which are multinucleated.

Encephalitozoon cuniculi is a microsporidial organism that is a rare cause of placentitis and abortion in a wide range of animals, including horses. A Quarter Horse mare aborted a fetus and placenta 6 weeks before term; viscous yellow exudate was scattered over the chorionic surface of the placental body and both horns. In addition, the joints of the foal were swollen and contained tan to red gelatinous material. On microscopic examination, there was necrotizing placentitis and trophoblasts contained large numbers of intracytoplasmic vacuoles that were filled with elongated gram-positive organisms. These were positively identified by polymerase chain reaction and electron microscopy as *E. cuniculi*. No organisms were identified in the joints.

Mycotic abortion in cattle

Sporadic cases of bovine abortion occur due to infection with a variety of fungal species, with *Aspergillus fumigatus* the most frequent isolate. Zygomycetes (*Absidia, Mortierella, Rhizomucor, Rhizopus*) are also commonly responsible. Mixed fungal infections are relatively common, in which case both septate and nonseptate hyphae may be observed in the placenta. A small number of abortions result from *Pseudallescheria boydii* and yeast (*Candida, Torulopsis*) infections. The portal of entry is not known, but the initial development of lesions in placentomes indicates *hematogenous arrival*. Extension from either respiratory or rumen infections is possible. With the exception of *Rhizopus*, these organisms are well-known secondary pathogens. Abortion occurs late in gestation, between the sixth and eighth month, and the placenta is often firmly retained.

The fetus may appear normal, but often there are characteristic cutaneous lesions in the form of irregular elevated plaques resembling ichthyosis or extensive ringworm. These lesions are seen most commonly about the periorbit, occiput, shoulders, back, and sides (Fig. 4.109). Affected

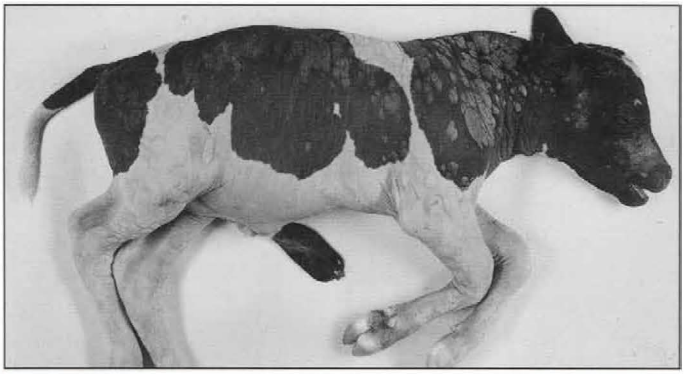

Figure 4.109 Mycotic dermatitis in a fetal calf in mycotic abortion from a cow.

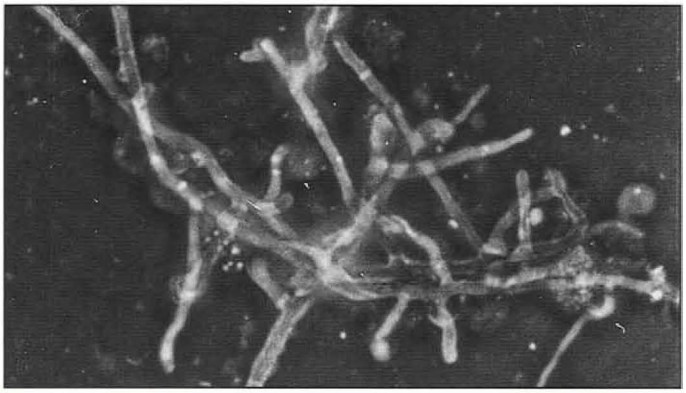

Figure 4.110 *Aspergillus* sp. in smear from fetal stomach (phase-contrast microscopy) in mycotic abortion from a cow.

areas are slightly elevated, gray, and irregular in outline and tend to coalesce. Histologically, the infection is seen to be superficial, involving the epidermis mainly, with parakeratosis, and edema and inflammatory cell infiltration of the underlying dermis. Sometimes the fungus invades the hair follicles and dermis but, with the exception of an occasional case of bronchopneumonia, there are no lesions in the internal organs. The fungus can be isolated from the stomach contents (Fig. 4.110). *The placental lesions are remarkable.* The gross appearance resembles that seen in brucellosis but is often much more severe. The allantois-chorion is then leathery with extensive superficial necrosis. The placentomes are greatly enlarged and necrotic with swollen margins, and are firmly incarcerated (Fig. 4.111). *The infecting organisms are readily demonstrated in the necrotic tissue*, and typically extend along the blood vessels to produce necrotizing vasculitis.

Lesser degrees of placentitis are probably quite common, with the lesions restricted to placentomes as areas of hemorrhage, softening, and necrosis (Fig. 4.112). The infection appears to begin in the placentomes, with later spread to the interplacental space between the cotyledons, where a rich growth of hyphae occurs. With placentitis of lesser degree, there are usually no cutaneous lesions in the fetus, although the fungi can be found in the gastric contents. The endometrial lesions are less severe than those in the placenta. Secondary infections may follow retention of the placenta. The majority of cows recover sufficiently after abortion to allow subsequent pregnancies to be carried to term, but in some, endometrial destruction is severe.

Epizootic bovine abortion

This disease is a tick-borne infection of cattle that produces chronic fetal disease and abortion. The name is a misnomer, as epizootic bovine abortion (EBA) is actually provincial and endemic. Its distribution is apparently limited by that of the vector, the argasid tick *Ornithodoros coriaceus*. The precise geographic range of the tick is not known. It is known to inhabit brushy foothills of California and adjacent areas of Nevada, Oregon, and northern Mexico. The most common hosts of the tick are cattle and deer. The tick is presumed to transmit an agent from the deer to cattle, as the infection remains endemic in ranges on which no cattle have been grazed. *The cause of EBA is unknown; the primary suspect is the spirochete Borrelia coriaceae.* Although this spirochete has been detected in salivary glands and other tissues, in a high percentage of adult *O. coriaceus* ticks in areas endemic for EBA, isolation attempts have been unsuccessful. The search in the infected fetus has narrowed on the thymus primarily.

Cattle exposed to the ticks for the first time are primarily at risk. *The infection produces no recognizable clinical signs in cattle of any age, but if the animals are pregnant, especially at 2–6 months, the infection is passed to their fetuses, where a chronic disease develops.* The fetus at this stage of gestation has not fully developed a functional immune system. This, coupled with a cow that has not been previously exposed to the agent, allows the agent to cross the placenta to the fetus and initiate chronic infection. There is a 3-month or longer incubation period between the exposure of the dam to ticks, development of the entire spectrum of lesions, and death and abortion of the fetus. Since the lesions gain their specificity only during the latter part of this prolonged period, the disease can only be confidently diagnosed in those animals exposed before the last trimester.

Not all diseased fetuses are aborted. The fetus is likely to have developed a functional immune system by 7–8 months of gestation, and may not be aborted if infected by the agent in that time period. Instead, the calf may not die from the infection but be born weak. *Weak calves* are often seen associated with outbreaks of abortion in this disease. Cows that abort due to the disease are not usually ill and the placenta is shed without difficulty. Cattle develop immunity and do not abort even if they are re-exposed to the ticks and the agent they carry. If there is little movement of animals, abortions may be rare in endemic areas. The disease becomes a major cause of abortion in a herd only when pregnant nonimmune animals are moved into an area where the infection is endemic.

The fetuses affected by the disease are most often aborted during the last trimester. Most trigger their own deliveries and die either during delivery or shortly thereafter. Only rarely do they die in utero and undergo autolysis. Many, but not all, affected fetuses have characteristic abdominal distension due to ascites, which is a striking, but inconstant, lesion. Lymph nodes throughout the carcass are enlarged, usually impressively so. The normal superficial cervical lymph node of a term bovine fetus weighs between 3.5 and 7.0 g. Fetuses aborted in this disease have cervical lymph nodes that weigh 16 g or more. The prescapular lymph node is especially easy to see beneath the skin immediately in front of the shoulder blade. The spleens of affected fetuses are similarly enlarged; the thymus, in contrast, is reduced in size.

Petechial hemorrhages are regularly seen in the conjunctival and oral mucosa as well as in the mucosa of the trachea. The thymus is often embedded in massive hemorrhages and edema. These hemorrhages are, at least in part, traumatic, developing during parturition, the portion of the thymus within the thoracic cavity being spared. The *enlarged, coarsely nodular liver* is, when present, an impressive gross change in fetuses affected by EBA (Fig. 4.113). However, the lesion is not present in all diseased fetuses, and similar hepatic congestion with ascites occurs in fetuses with cardiac anomalies. Many aborted fetuses breathe, and the lungs of these are partially aerated. Small gray foci of inflammation can be seen in a variety of tissues, but are most conspicuous in organs such as kidney and heart that provide a dark background.

The changes that develop in the lymphoid organs are the most specific and diagnostic. *The enlargement of lymph nodes and spleen consists of remarkable lymphoid and mononuclear cell hyperplasia.* Well-defined secondary follicles develop in the cortical and paracortical regions of the lymph nodes. The sinuses are stuffed with macrophages that form sheets in the medullary areas (Fig. 4.114). The spleen shows a similar hyperplastic response involving lymphocytes of the follicles and periarterial sheaths; there is also widespread infiltration of macrophages. Foci of acute necrosis are often superimposed on the chronic proliferative change (Fig. 4.115).

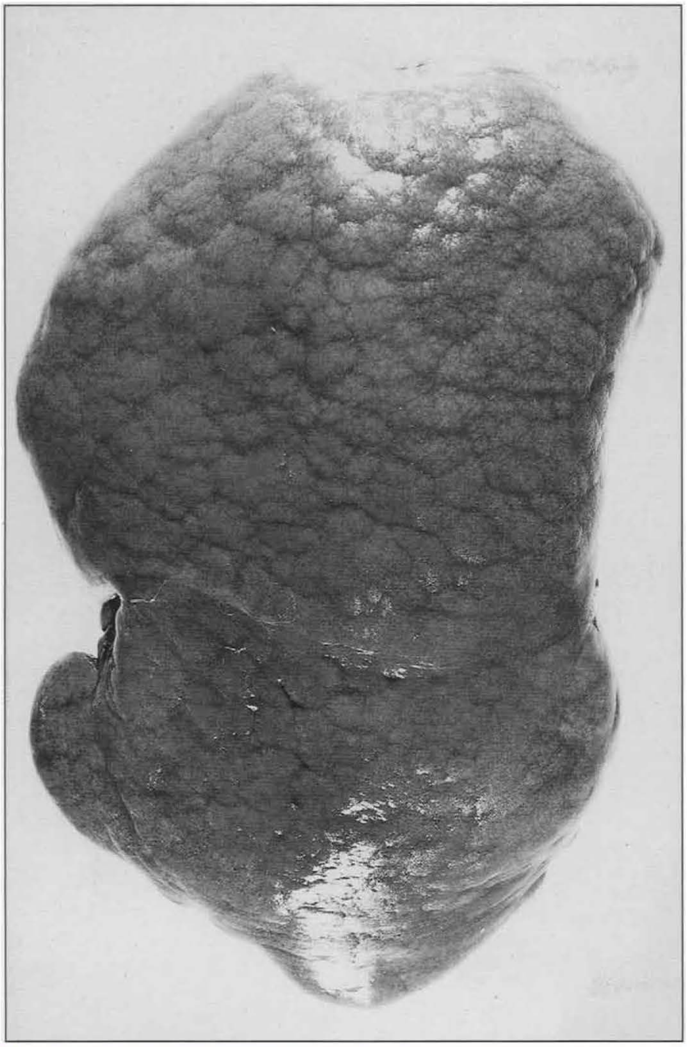

Figure 4.113 Congestive nodularity of liver in an aborted fetus, in epizootic bovine abortion.

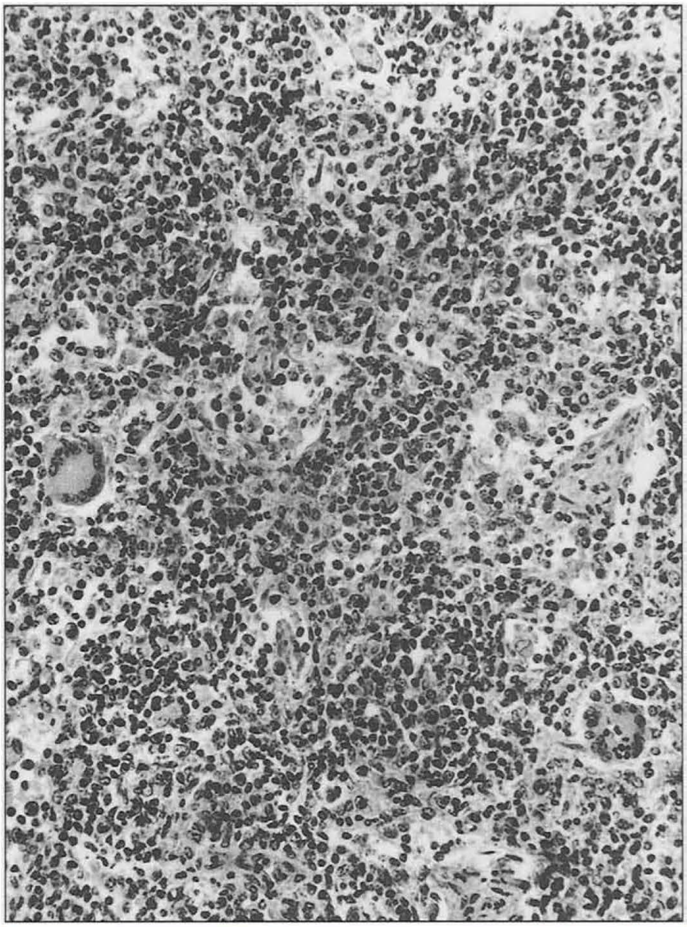

Figure 4.114 Proliferative lymphadenitis with giant cell formation in an aborted calf, in epizootic bovine abortion.

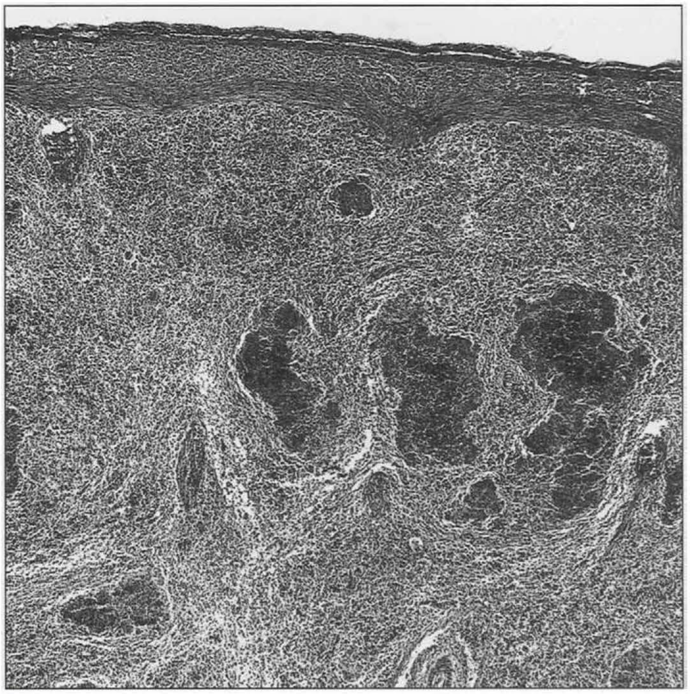

Figure 4.115 Focal areas of **acute necrotizing splenitis** in a fetus, in epizootic bovine abortion.

The most distinctive fetal lesion is a *remarkable thymic inflammatory change*. The cortical mantle of thymocytes is greatly reduced, and macrophages diffusely infiltrate both the medulla and the septa of the gland (Fig. 4.116). The central veins of the liver are distended and the liver plates thinned. Mononuclear cell infiltration is present around portal vessels. Foci may be 100 μm in diameter and are often granulomatous in appearance.

Affected fetuses may have vasculitis involving small- and large-caliber vessels in any, or all, organs (Fig. 4.117). Lesions that are particularly useful in establishing the diagnosis are regularly present in the lung and brain. The alveolar walls of the lung are thickened, and granulomatous inflammatory foci are present in the septa. In the brain, foci of vasculitis are scattered throughout and the meninges are thickened by granulomatous inflammation (Figs 4.118, 4.119).

Lesions do develop in the placenta but are usually mild and involve the loose connective tissue. They contrast with the acute severe inflammatory reaction of the chorionic surface seen in bacterial and *Chlamydophila* infections.

Diagnosis of EBA is based on a combination of gross and histologic findings in an aborted fetus in the geographical area endemic

Protozoan infections causing abortions

Toxoplasmosis

Infection with ***Toxoplasma gondii*** appears to be very common in many species, but the disease toxoplasmosis is much less common and its diagnosis is still somewhat of an event. The present discussion is limited to genital manifestations. A more complete discussion of the disease is given with coccidial disease of the intestine (see Vol. 2, Alimentary system).

Toxoplasma is second only to *Chlamydophila* as a cause of fetal death and resorption, abortion, or stillbirth in sheep, and is also an important abortifacient in goats; both pathogens may occur simultaneously in the same abortion outbreak. Animals that are particularly at risk of *Toxoplasma* abortion are those moved late in pregnancy to areas heavily contaminated with cat feces. This occurs most often when ewes are housed in barns. Under such circumstances abortion rates can be high. Although *Toxoplasma* can cause abortion, congenital transmission from ewe to lamb also occurs in a high percentage of normal healthy lambings.

The ewes and does show no signs of infection. The aborted lambs and kids show no significant gross lesions; in only a few are lesions and parasites demonstrable histologically in myocardium, lung, and brain. Irregular small or large foci of leukomalacia are common in the hemispheral white matter. *The fetal placenta bears what are probably characteristic lesions*. The cotyledons are bright to dark red as compared with a normal deep purple color; scattered amongst the fetal villi are *numerous white flecks or small soft white nodules* 1–3 mm in diameter (Fig. 4.120). The villi are edematous, and there is focal necrosis and desquamation of trophoblastic epithelium. In some there may be caseous and calcified cotyledonary nodules. The organism is identified either free or in pseudocysts. The intercotyledonary placenta shows edema only. Encysted organisms can frequently be found in the endometrium. It may be assumed that placental infection can occur at any time the infection is active and the organism is in the proliferative phase.

Cattle rarely, if ever, abort due to toxoplasmosis. Although the organism may be present in cattle, it does not appear to cause disease. *Toxoplasma* has been reported to cause abortion in *swine*, with fetal lesions, but this appears to be an uncommon event.

Neospora infections causing reproductive failure in cattle, sheep, dogs, and cats

Neospora is a newly recognized protozoan parasite belonging to the class Apicomplexa. *N. caninum* was first isolated from a litter of puppies, and domestic dogs are the only recognized definitive hosts of the parasite. *It is a major cause of abortion in both dairy and beef cattle throughout the world.* Although observed in tissues from aborted bovine fetuses for many years, the organism was first associated, and in 1987 identified, as the cause of an abortion storm in cattle in New Mexico. It differs morphologically and antigenically from *Toxoplasma* and *Sarcocystis*.

The organism can cause severe neuromuscular paralytic disease in dogs and cats. Experimentally induced infections in pregnant dogs and cats lead to in utero death and birth of infected offspring, some of which die while others remain normal. Orally induced infection in nonpregnant cats subsequently bred results in clinically normal young, born infected with the parasite.

In **cattle**, the natural route of infection is probably by consumption of oocysts excreted in the feces of dogs and other canids. Eating infected carcasses or placentas from infected fetuses may infect canids. Most reports of abortion involve dairy cattle and particularly cows on drylot. This is believed to be associated with the density of population and methods of feed storage providing increased opportunity for contamination, transmission, and spread of the organism. Beef cows however also abort. Conception does not seem to be affected; however, animals have been reported to abort with *Neospora* in three sequential pregnancies. Abortion storms, where fresh or autolysed fetuses are aborted, may be followed by the birth of mummified fetuses for several months. Animals aborting in one year may or may not abort in the next gestation. Herd investigations have

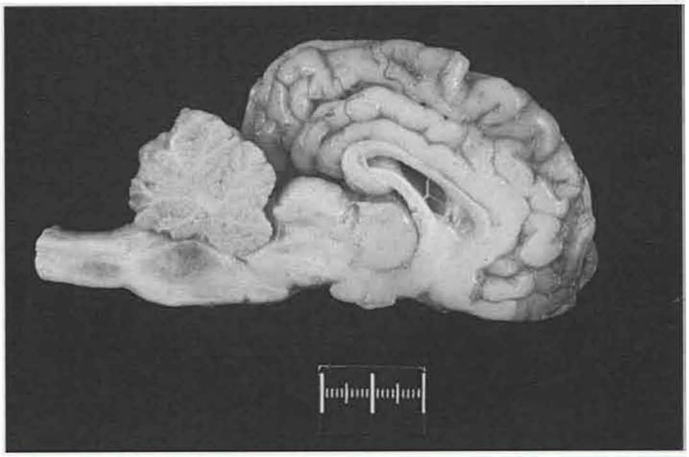

Figure 4.121 Focal malacic lesions in a fetal bovine brain, due to *Neospora* infection.

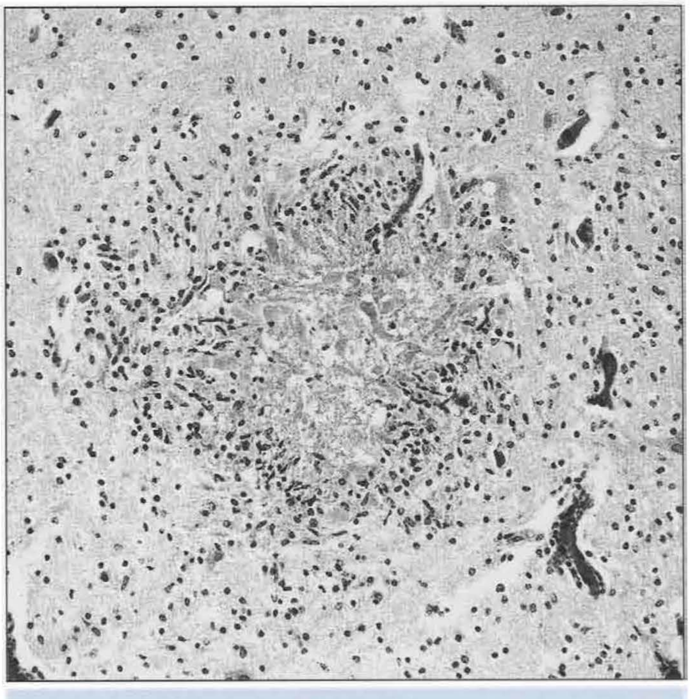

Figure 4.122 Focal necrosis surrounded by narrow zone of glial cells in fetal bovine brain, due to *Neospora* infection. (Courtesy of Barr BC and Vet Pathol 1990;27:354–361.)

shown that 23% of pregnant cows and heifers abort during the first year of infection. Although protective immunity develops in infected cows, this immunity does not prevent transplacental infection, and seropositive cows are more likely to abort than are seronegative cows. Seronegative cows probably always produce seronegative calves. Most *Neospora*-induced abortions occur at 5–6 months of gestation; this mid-gestation abortion frequency is distinctive from other kinds of abortion in dairy cattle. Pregnancy-induced immunosuppression is a possible, but unproven, cause of reactivation of latent *Neospora* infections. The economic impact of *N. caninum* infection in dairy cattle extends beyond that from abortion to include premature culling due to the diminished milk production that occurs in seropositive cows. Cows infected with *Neospora* are usually not clinically ill, nor do they have an increased risk of dying compared to seronegative cows.

Congenitally infected full-term calves may not show signs of disease, but still have a high titer to the organism. *Neospora*-infected calves may be born small-for-gestational-age, unable to rise, ataxic, or have no clinical signs. Fore- and hindlimbs may be flexed or hyperextended; there may be loss of conscious proprioception.

On necropsy, *there are often no useful identifying gross lesions*. Bovine fetuses are often expelled in the second or third trimester and may be fresh, autolysed, or in early stages of mummification. In the placenta, the cotyledons are necrotic and the intercotyledonary region is normal. Rarely, there are scattered tan-to-gray soft foci visible in the brain, brainstem (Fig. 4.121), skeletal muscle, and heart. These consist of *necrosis, mononuclear cell infiltrates, perivascular cuffing, and sometimes mineralization* (Fig. 4.122). Cysts may be difficult to find or conspicuous, and are probably more common in spinal cord than brain. *N. caninum* invades many different cell types and tissues in the fetus (Fig. 4.123). The tachyzoites proliferate intracellularly by endodyogeny; massive proliferation leads to host cell lysis, and newly formed parasites are released to invade neighboring cells.

Neospora tachyzoites may be identified in focal brain lesions; however, *free protozoa are difficult to recognize and are most easily identified using immunohistochemistry*. Intracellular zoites may be seen in myocytes and Purkinje fibers in myocardium. Less consistent lesions include multifocal hepatic necrosis (Fig. 4.124), focal nonsuppurative interstitial nephritis, interstitial pneumonia, and adrenal adenitis. Large numbers of *N. caninum*-like zoites are rarely observed in poorly defined cysts within trophoblasts, and more often no significant lesions are seen in the placenta. Mononuclear cell infiltrates may be associated with areas of focal necrosis in the cotyledons. *Neospora*, although rarely identified in placenta by immunohistochemistry, may be positive on polymerase chain reaction.

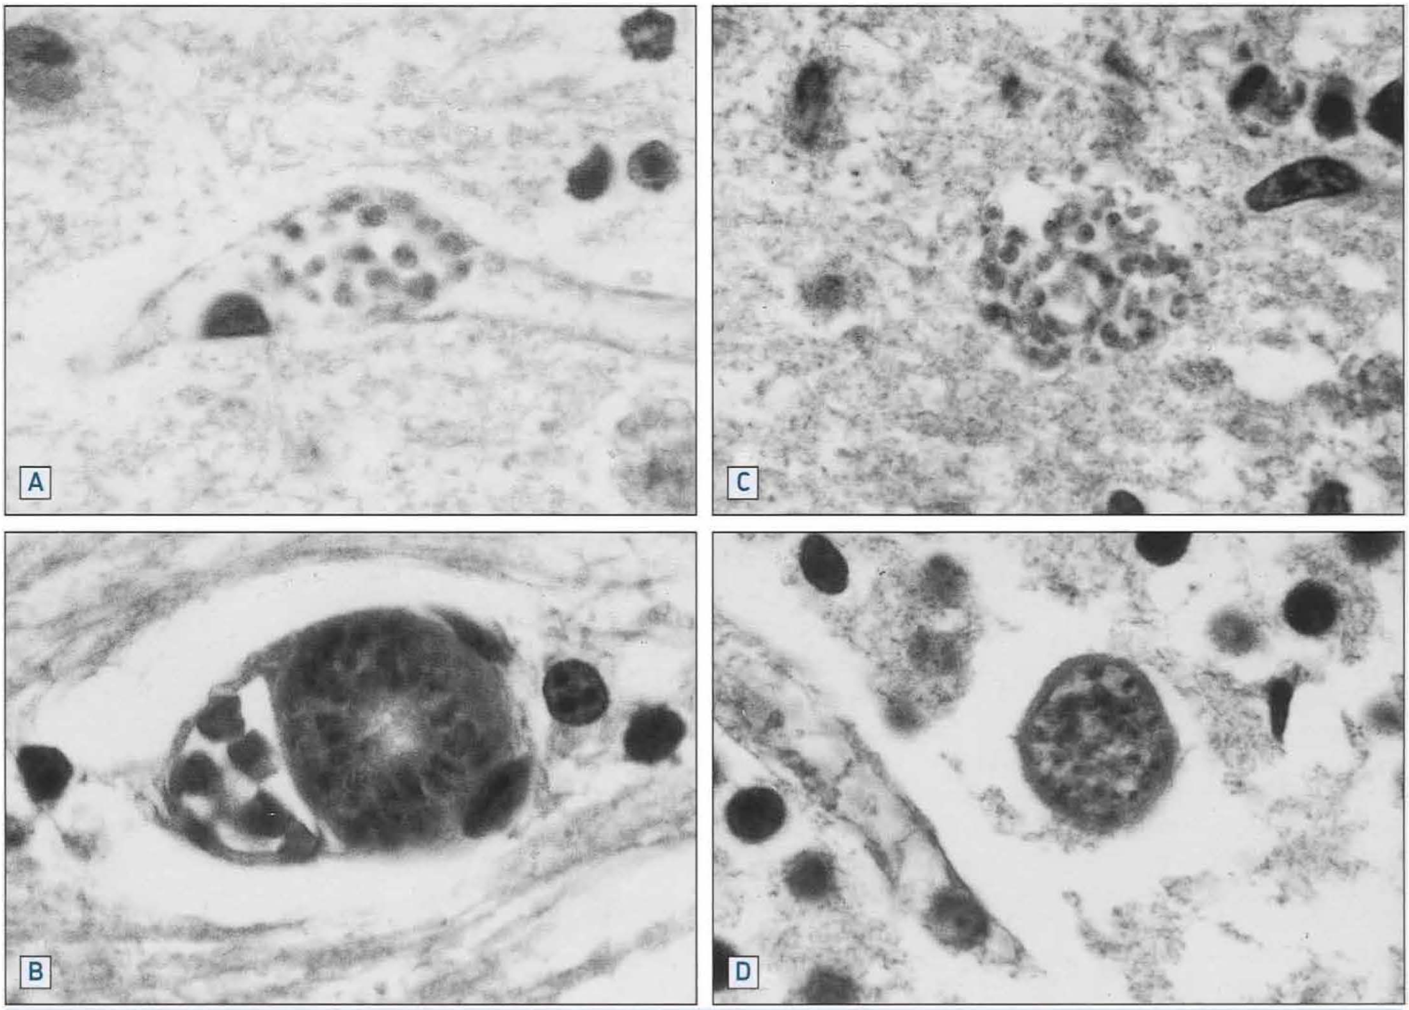

Figure 4.123 **A.** Cluster of ***Neospora* zoites** in fetal brain capillary. **B.** Cluster of *Neospora* zoites within an endothelial cell. **C.** Cluster of *Neospora* zoites lying free in brain parenchyma. **D.** Cluster of *Neospora* zoites surrounded by cyst-like wall in brain parenchyma. Figure 4.125 Immunohistochemically stained section of fetal bovine brain demonstrating ***Neospora*** organisms in a neuron. (Courtesy of Debbie Haines.)

On light microscopy, *N. caninum* can be distinguished from cysts of *Toxoplasma* and *Sarcocystis*, as the cyst wall is slightly thicker. *All stages can be differentiated from other protozoans using immunohistochemistry*, which is successfully used to demonstrate protozoa in brain (Fig. 4.125), spinal cord, lung, kidney, heart, and skeletal muscle of fresh or autolysed fetuses and also, but with more difficulty, in mummified fetuses. Isolation of *Neospora* from autolysed tissues in cell cultures is rarely successful because of the effects of autolysis. Tissue cysts may be rare in in utero-infected fetuses; however, serology on fetuses aborted at greater than 5 months' gestation has proved useful in detecting antibodies to *Neospora*. Maternal antibodies to *Neospora* may also be detected but decline within 2–5 months of abortion.

N. caninum has also been identified as a cause of abortion in **sheep** and possibly in **goats**. Lesions appear to be similar in bovine and ovine aborted fetuses, and clinically affected bovine, ovine, canine, and feline neonates. The role of *Neospora* (*N. caninum* or *N. hughesi*) in **equine** abortions is under investigation.

Sarcocystis species causing abortion in cattle, goats, sheep, and pigs

Sarcocystis species cause abortion, stillbirth, and neonatal deaths in cattle, goats, sheep, and pigs. In contrast to some of the other protozoa, they are usually specific for their intermediate host and may be named using the intermediate and definitive host in the species name; for example, *Sarcocystis bovicanis (*syn. *S. cruzi)*, *Sarcocystis capracanis (*syn. *S. tenella)*. Transmission, pathogenesis, lesions, and diagnosis are similar in all intermediates, and only lesions observed in cattle will be described. Ingesting food or water contaminated by feces containing oocysts, which are immediately infective to the intermediate host, infects the animal. Definitive hosts include the dog, coyote, wolf, red fox, and raccoon for the pathogenic organism *S. bovicanis*.

The pathogenesis of *Sarcocystis*-induced abortion is uncertain, but may involve anemia in the dam leading to fetal hypoxia and death,

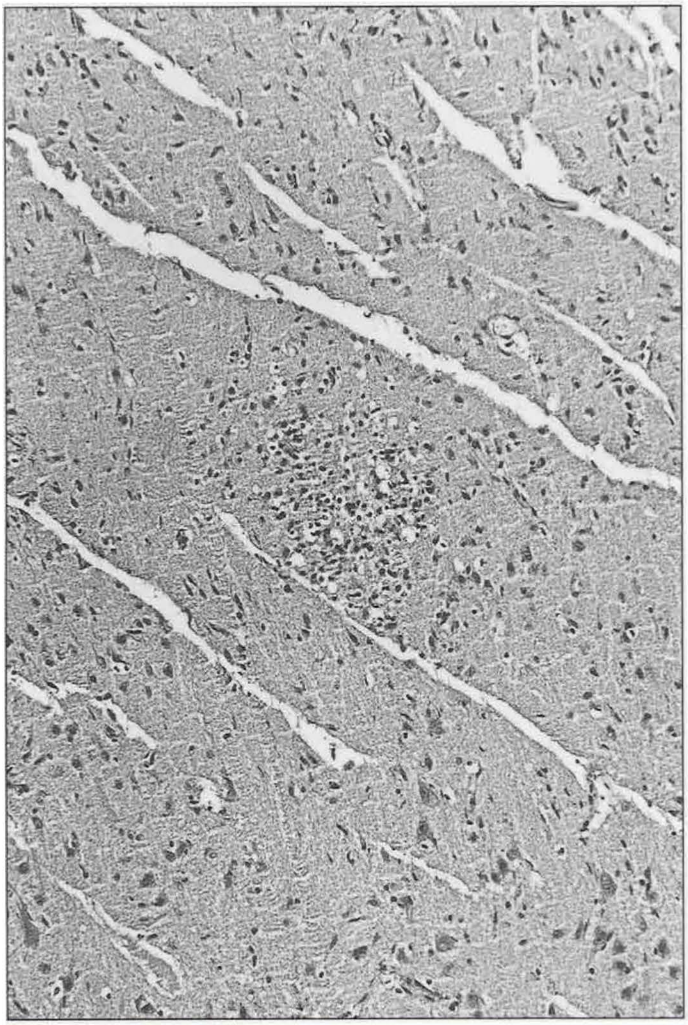

Figure 4.126 Nonsuppurative encephalitis in *Sarcocystis* abortion of a bovine fetus.

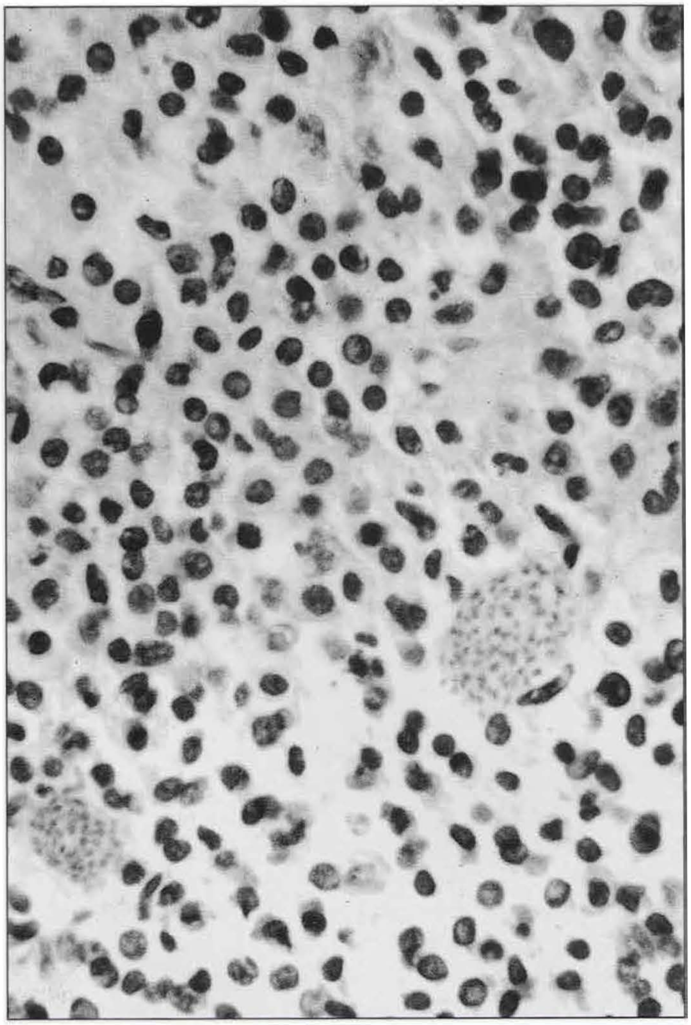

Figure 4.127 Sarcocyst in endothelium of small vessel in Peyer's patch of a bovine fetus.

premature induction of parturition through release of prostaglandin $F_{2\alpha}$ from damaged endothelial cells, fever, or direct infection of the fetus. Infection in the dam may result in acute necrotizing endometritis followed by multiple foci of necrosis in the soft tissues of the fetus. Why the organism is sometimes visible only in the dam but at other times also in the fetus is not known. In the dam, the zoite-containing cysts may be observed in the endometrium or caruncle following abortion, but if it passes to the fetus, in spite of autolysis and near absence of gross lesions, extensive lesions are evident microscopically. In the brain and meninges, there are multifocal areas of necrosis surrounded by undifferentiated mononuclear cells and lymphocytes (Fig. 4.126). Cardiac muscle, kidney, liver, lung, and chorioallantoic membranes may have similar lesions, some of which are mineralized and undergoing fibrosis. Endothelial cells in several soft tissues may contain thin-walled cysts that bulge into the lumen (Fig. 4.127) of the frequently thrombosed vessel. The cysts, packed with elongate zoites, though often difficult to find, are most easily distinguished in nervous tissue, maternal caruncle, and endometrium away from the site of inflammation.

Diagnosis is based on finding typical lesions of nonsuppurative meningoencephalitis, multifocal necrosis in soft tissues, and the presence of cysts containing zoites with a tropism for endothelium. If the organism cannot be found on routine sectioning, it can readily be located using specific fluorescent antibody, immunogold, or avidin–biotin complex techniques.

Genital tritrichomoniasis

This is a specific contagious venereal disease of cattle caused by the flagellated protozoan *Tritrichomonas foetus* and transmitted at coitus or artificially via contaminated semen.

Infection in the bull remains in the preputial cavity and must be considered, in the absence of effective treatment, as permanent. In early infections, there is a balanoposthitis of moderate severity with preputial swelling and a slight purulent discharge. As the infection becomes chronic, the inflammatory reaction disappears and the organisms become fewer in number. There is a tendency for them to concentrate on the glans penis and adjacent areas of the prepuce, but they are quite difficult to find in preputial washings and may be detected only by test-mating suspected bulls to susceptible heifers.

Females are not readily infected, if at all, except by service or experimentally by placing a culture of the organism in the vagina. A few days after infection, acute vaginitis with swelling of the vulva develops and there is a moderate amount of mucoid floccular discharge in the vagina. The protozoa may be easy or impossible to find in this exudate. The vaginitis resolves shortly, and the infection localizes in the uterus and cervix. Immediately prior to the estrus, which follows the infective service, large numbers of organisms can usually be found in exudate aspirated from the cervix, but as estrus advances the number of protozoa is greatly reduced.

The manifestations of established trichomoniasis in females are cervicitis and endometritis that result in repeat breeding, abortion, or pyometra. The inflammatory changes in the endometrium and cervix are relatively mild and nonspecific, although the mucopurulent exudate may be rather copious. Discharge of exudate into the vagina may be more or less continuous or intermittent, and the numbers and activity of the trichomonads in the discharge vary considerably over short periods. The discharge may not be apparent at the vulva.

The pattern of repeat breeding in tritrichomoniasis is the same as that in venereal *Campylobacter* infections. Return to service occurs at irregular intervals, a fact that indicates that fertilization and implantation are followed by embryonic death. When the embryo or fetus dies, it may be resorbed, aborted, or retained with the development of pyometra. Trichomonad abortions may occur at any time, but mainly in the first half of pregnancy. *There are no specific fetal lesions, but large numbers of protozoa may be found in the fetal fluids and stomach.* The placenta is not severely altered as in brucellosis; it may be covered by white or yellow flocculent exudate in small amounts, thickened and slightly tough; hemorrhage without much necrosis may be evident on the cotyledons. Pyometra is one of the remarkable changes of trichomoniasis, but it is a relatively uncommon complication. Its pathogenesis follows the scheme outlined earlier, and its character is remarkable only for the copiousness of the exudate; any volume up to 4 liters or more may be present. The exudate may be watery with floccules, colostrum-like, or brown and sticky. It is without odor and swarms with trichomonads.

Viral infections of the pregnant uterus

Porcine reproductive and respiratory syndrome (PRRS)

The syndrome has gone under various names such as "blue ear," because of ear discoloration in the pneumonic form, and "mystery swine disease" when the cause was yet to be identified. The syndrome is caused by *Porcine reproductive and respiratory syndrome virus* (PRRSV), family Arteriviridae, genus *Arterivirus*, a positive-strand RNA virus. All ages of nonimmune pigs are affected. Death rates can be high in piglets born with pneumonia or infected before or after weaning. Deaths in piglets are also associated with secondary bacterial infections, including *Salmonella choleraesuis*, *Streptococcus suis*, *Actinobacillus pleuropneumoniae*, and *Haemophilus parasuis*. These secondary infections often account for major reproductive losses. Viremia and circulating antibodies may coexist. Strain differences may account for some of the reinfections. Nonimmune animals vaccinated with modified-live PRRSV vaccines may experience increased abortions, stillbirths, and high mortality in newborns.

The effects of PRRSV on reproductive performance are variable between strains, and even though a gilt develops antibodies to one strain she may be susceptible to another. Similar differences in pathogenicity occur in respiratory disease. Effects also vary greatly depending on the stage of gestation and may result in early farrowing of stillbirths and mummified fetuses.

Initial clinical findings in infected pregnant gilts are anorexia, lethargy, depression, and mild fever; cyanosis of the snout, ears, tails, vulva, and abdomen occurred commonly in European outbreaks but are rarely observed in North America. This is commonly followed by a sudden increase in *early farrowing, late-term abortions, stillbirths, mummified fetuses, infertility,* and sometimes death. Live piglets with respiratory signs, muscle tremors, and splayleg also occur. Transplacental passage may result in fetal antibody production. After an outbreak of reproductive failure, previous levels of reproductive performance may not be achieved. Variable degrees of endometritis and myometritis may be present.

Gross and microscopic lesions in piglets are variable to absent and often obscured by autolysis. "Paintbrush" hemorrhages have been observed on the placenta and petechial hemorrhages, and necrosis occurs on umbilical vessels, skin, and renal cortex. Microscopic lesions include lymphoplasmacytic and histiocytic infiltrates within and around small capillaries at the periphery of the tunica adventitia of umbilical arteries. Mild to moderate, multifocal to diffuse, histiocytic and proliferative interstitial pneumonia characterized by mononuclear cell septal infiltration is commonly observed. Hypertrophy and hyperplasia of type 2 pneumocytes is occasionally present. Mild segmental necrotizing and lymphohistiocytic arteritis has been seen in lungs. Mild segmental necrotizing and lymphohistiocytic, suppurative and, less often, eosinophilic hepatitis may be present. Mild multifocal perivascular lymphohistiocytic myocarditis and, rarely, multifocal myocardial hemorrhages are present.

The **diagnosis** *is established by isolating the PRRSV, polymerase chain reaction (PCR) assay, or by in situ hybridization or immunohistochemical (IHC) detection of the virus in formalin-fixed tissues.* Immunogold has been found to be superior to immunoperoxidase as a marker. The virus is rapidly inactivated in aborted, stillborn, or mummified fetuses and isolation is therefore inconsistent. However, reverse transcriptase PCR testing modalities appear to be impacted the least by the adverse effects of autolysis. PCR becomes valuable in diagnosis as there are no consistent gross or microscopic lesions of this syndrome in fetuses and in utero autolysis rapidly inactivates the virus and interferes with isolation from aborted transplacentally infected fetuses.

Classical swine fever virus infections of the pregnant uterus in sows

Classical swine fever virus (CSFV, syn. Hog cholera virus), a pestivirus, family Flaviviridae (single-stranded, positive-sense RNA genome), is a serious and contagious viral disease of swine; fortunately it has been eradicated from many countries. *Pestiviruses include CSFV, Border disease virus (BDV) of sheep, and Bovine viral diarrhea virus (BVDV). Infection by any of these three viruses can have similar results,* namely early embryonic losses due to in utero transmission to the fetus, severe congenital abnormalities and, particularly with BVDV, lifelong persistent infections.

The virulence of CSFV varies from avirulent to highly virulent. Pigs infected with highly virulent CSFV may have a high fever, depression, incoordination, reddening of the skin, diarrhea, respiratory distress, and death associated with widespread hemorrhage due to *severe necrotizing vasculitis*. Moderately virulent and virulent strains of CSFV cause subacute and chronic disease, with similar but milder signs. *During an inapparent viremic phase in a pregnant sow, the virus may be carried to the fetus and result in embryonic death, malformations, mummification, or stillbirth, or birth of live clinically normal pigs or pigs with tremors. Persistently infected piglets* may be born at term and appear clinically normal or weak but, in either circumstance, eventually succumb to the effects of the virus.

The virus can be transmitted from carrier or clinically affected pigs through their secretions and excretions, or through the ingestion of contaminated wastes. Birds, parasites, and fomites have also been identified as the source of virus in outbreaks. At one time, the use of vaccines containing CSFV of low virulence was the cause of severe losses due to in utero infections in pigs.

After exposure of a pregnant sow, the virus multiplies in the tonsils and spreads to other lymphoid organs, eventually reaching the fetus between 13 and 18 days. During the viremic stage, the virus crosses the uteroplacental interface infecting, all or only some fetuses. In the latter situation, the virus may continue to pass from fetus to fetus in utero, eventually infecting many.

Lesions produced in a fetus following in utero infection are very variable and depend on the virulence of the infecting virus, the stage of gestation when the infection occurs, and an apparent variation in the development time of immune competence to CSFV in fetal piglets. Generally, and with many exceptions, early infections result in embryonic or fetal death or persistent infections. Early to midgestation infections result in *malformations*, including pulmonary hypoplasia, pulmonary artery malformation, microagnathia, arthrogryposis, and central nervous system malformations (including cerebellar hypoplasia, microcephaly, and defective myelination in brain and spinal cord). Infections during the last trimester may produce no abnormalities, or may result in mummification or stillbirths.

Persistent infections in piglets most commonly follow exposure to the virus from 22 to 70 days of gestation and, rarely, up to 100 days. These fetuses may or may not die in utero and often show retarded development and runting. Many show no signs until some time after birth and persistently infected pigs living to 11 months have been reported. The latter commonly have marked depletion of lymphocytes (especially in the thymic cortex), and B-cell-dependent regions of lymph nodes and spleen. Lesions are also observed in heart (degeneration of endothelium and valvular fibrosis), liver (portal fibrosis), intestine (villus atrophy and ulceration), lungs (interstitial pneumonia), skin (necrosis and degeneration of epithelial cells), and central nervous system (neuronal degeneration and hydrocephalus). Many persistently infected piglets are born alive with a congenital tremor associated with central nervous system dysgenesis, cerebellar hypoplasia, and hypomyelination. Piglets with tremor, which survive for long periods, have reduced clinical signs but continue to excrete CSFV. The similarity of this to the syndrome in border disease virus-infected "shaker lambs" suggests a similar pathogenesis.

Many fetal piglets show some ability to respond immunologically to CSFV between 70 and 90 days of gestation with an immunoglobulin of low specificity and avidity. In accordance with this, fetuses collected from sows infected during this period may show general lymphoid hyperplasia and development of primary follicles. Kidney and brain may have mild lesions with scattered focal mononuclear cell infiltrates, and spleen and kidney may have foci of necrosis and hemorrhage.

For **diagnosis**, CSFV can be isolated from a variety of fetal tissues, including the placenta, and from the serum of persistently infected swine. Fetal antibody may be present in late-gestation fetuses, but carrier sows may or may not have antibody. In addition, the virus may be identified by the fluorescent antibody technique in tissue sections. In some laboratories, monoclonal antibodies to CSFV are routinely being used to differentiate CSFV from BVDV infections and, in some instances, CSFV vaccine strains from field strains. This may be very important in large eradication and control programs.

Bovine viral diarrhea virus infections of the pregnant uterus

Bovine viral diarrhea virus (BVDV) is classified as genus *Pestivirus* in the family Flaviviridae. It is closely related to *Border disease virus* of sheep and less closely to *Classical swine fever virus*. For further discussion, see the section on *Border disease virus* infection in sheep and goats, below. *These three viruses have been shown to cross-infect naturally between species.* The various strains of BVDV, while similar, differ in virulence and can be distinguished antigenically. Two *biotypes* exist, one that is cytopathic for cell cultures (cp-BVDV = CB, cytopathic biotype), and one that is not cytopathic (ncp-BVDV = NCB, noncytopathic biotype). Both cause disease in cattle. In addition, there is *type 2 BVDV* that can infect fetuses, and exists in cytopathic and noncytopathic forms as well.

BVDV and *Akabane virus* are probably the most important viral pathogens of the bovine fetus. BVDV is distributed worldwide, and persistently infected cattle are reported to make up about 1% of the general population. They do not develop antibody to the homologous strain to which they are infected, but may respond to heterologous strains used in vaccines. Cattle persistently infected with ncp-BVDV or temporarily infected with cp-BVDV may excrete virus in feces, semen, urine, milk, nasal, ocular, and uterine secretions. Susceptible animals can acquire the virus by inhalation, ingestion, or when bred with contaminated semen. Cows may also become infected from contaminated embryo transfer fluids where serum from carrier animals is used. Cytopathic BVDV is derived from mutations of ncp-BVDV. *The ncp biotype may persistently infect the immunologically incapable fetus.* There is no report of a cytopathic biotype being isolated from an infected animal without the noncytopathic biotype also being present; the cp form has no means of maintaining itself in the population of animals without the ncp form.

Reproductive disease in cattle induced by BVDV includes oophoritis, fertilization failure, embryonic death, absorption or abortion, mummification, stillbirth, birth of calves small-for-gestational-age or with congenital defects, and weak calves or near-normal-looking calves born persistently infected (PI) with ncp-BVDV. Abortion storms can occur, and occasionally severe losses due to BVDV may follow superovulation and embryo transfer. This may be related to the creation of a population of fetuses of the same gestational age (and therefore equally susceptible to the infection), or contamination of transfer fluids by BVDV. Present evidence suggests that ncp-BVDV infects the bovine fetus following oronasal exposure of the dam, and only causes embryo injury when it mutates to the cp form of fetal infection.

Fertilization failure may occur when the virus is introduced in utero to seronegative cows. Conception and pregnancy rates in animals viremic at or shortly after insemination were approximately half of noninfected controls at gestation day 77. Surviving embryos were not infected. These data strongly support BVDV infection as being detrimental to early embryo development. Acutely infected bulls shed the virus in their semen for at least 14 days, and may have abnormal semen for several months. Spread of the virus is more likely to occur with natural service than with artificial insemination. Carrier and newly infected cows infect the fetus through the placenta. Bovine embryos or fetuses exposed to ncp-BVDV following viremia in the dam between 40 and 120 days of pregnancy may die and be absorbed, aborted, or mummified, supposedly following mutation to the cytopathic form. Fetuses dying from the infection may remain in the uterus for up to 50 days after death; recovery of the virus may be difficult.

In the period from 45 to 125 days' gestation, the ncp biotype will probably not cause fetal loss, but if it changes to the cp form, it may result in intrauterine growth retardation. Only the ncp biotype can cause persistent infection. If born alive, these PI animals constitute the main source of virus for other animals. *Central nervous system malformations* following infections with BVDV may continue to occur somewhat later in gestation than do infections resulting in persistent viremia. This is probably associated with the stepwise development of immune capability in the fetus along with the corresponding gradual development of its nervous system. Abnormalities attributed to BVDV include microencephaly, cerebellar hypoplasia, hydranencephaly, hydrocephalus, hypomyelinogenesis, myelination defects, microphthalmia, cataracts, retinal degeneration, optic neuritis, brachygnathism, thymic aplasia, hypotrichosis, alopecia, pulmonary hypoplasia, and growth retardation with growth-arrest lines in long bones. Porencephaly, hydranencephaly, and hydrocephalus have also been described, but the association with BVDV is less clearly documented. It is believed by some that only the cp biotype causes abnormalities. Cerebellar hypoplasia may be inapparent or severe. Normal and severely affected folia may be adjacent. Early lesions consist mainly of edema, hemorrhage, and necrosis of external germinal cells. Remnants of severely affected folia consist of fluid-filled cavities lined by flattened astrocytes surrounded by a thin layer of neuropil containing many hemosiderin-laden macrophages. Some folia have only reduced myelin content. Purkinje cells may be reduced in number and with a disorderly or absent external germinal cell layer. Perivascular accumulations of mononuclear cells and a few segmented cells may be present in neural parenchyma and meninges in cerebrum and cerebellum. Spongiform alterations of brainstem white matter have been recorded, along with spongiform alteration and liquefactive necrosis of ventricular funicular white matter in the spinal cord. Focal malacia of the ventral horns occurs following degeneration of ventral horn neurons along with glial satellitosis. Cataracts and retinal atrophy may be present in the eye, and the latter is presumed to follow focal-to-diffuse necrotizing, nonsuppurative retinitis and usually accompanies the cerebellar lesions. Microphthalmia and optic neuritis with subsequent atrophy also occur.

Other lesions associated with BVDV infections in the fetus include thymic cortical atrophy (with only epithelial stroma and macrophages persisting in the cortex), multifocal myocarditis, peribronchiolar lymphoid hyperplasia, pulmonary hypoplasia, multifocal perivascular dermatitis, and hypotrichosis. Cellular accumulations are usually mononuclear, lymphocytic, and plasma cell-rich. Plasmablasts, plasma cells, and lymphoblasts may be prominent in lymphoid tissues.

Antibody in fetal fluids and culture of virus from fluid and tissues are sensitive methods to determine if fetal infection has occurred. The presence of specific antibody in an aborted fetus only indicates the fetus was infected in utero. Fluorescent antibody and immunohistochemical detection of virus are frequently used to indicate the association of the virus with a lesion.

Border disease virus infection in sheep and goats

Border disease virus (BDV), *Classical swine fever virus* (CSFV), and *Bovine viral diarrhea virus* (BVDV) are in the family Flaviviridae, genus *Pestivirus*. All are related antigenically and cause significant disease in animals. BDV and BVDV are closely related, while CSFV is distinct. Some strains of BDV appear to be more closely related to certain strains of BVDV than to other strains of BDV, while others cannot be differentiated from each other. BDV, BVDV, and CSFV have been shown to cross-infect between species and this may occur naturally. Border disease is the result of in utero infection of pregnant sheep or goats by BDV; prevalence of BDV is variable in sheep and rare in goats. *Infection can result in embryonic or fetal death, abortion, mummification, dysmorphogenesis, early postnatal death, and birth of weak or clinically normal young.* Clinically normal kids or lambs can be persistently infected (PI). Infection in the nonpregnant adult animal may result in fever and leukopenia, but clinical signs are usually absent.

Transmission of BDV is believed to occur mainly between sheep; however, natural and experimental infections of BVDV from cattle to sheep have been reported and can cause BDV outbreaks. BDV can be transmitted by oral, conjunctival, intranasal, and genital routes. *As congenitally infected sheep can have lifelong viremia, they are probably the main reservoir for the virus.* PI ewes can transmit the virus to their fetus through the placenta (over several pregnancies), and in rams, the virus has been observed in the seminiferous tubules of the testes and can be transmitted in the semen. BDV has been demonstrated in the germinal cells of the ovaries of sheep; the significance of this site in the transmission of the virus is not known.

A wide variety of fetal tissues are affected by BDV infection, and the name "*hairy shaker*" was coined because of the frequently observed hairy appearance of the wool and the tremor associated with hypomyelinogenesis. Abnormalities induced in the fetus, as in cattle, depend mainly on the stage of gestation, and reflect the stepwise development of fetal immunocompetence to the virus. Strains of the virus also vary in virulence, as does the susceptibility of breeds of sheep to the effects of the agent. As the ovine and caprine fetus becomes immunocompetent to BDV by about 90 days, most injury follows infections occurring before this time.

Central nervous system lesions include hypoplasia and dysplasia of the cerebellum, microcephaly, porencephaly, hydranencephaly, leukoencephalomalacia, and reduced weight and length of the spinal cord. The most consistent lesion is *dysmyelination or hypomyelination*, and usually occurs without signs of inflammation.

The mechanisms responsible for hypomyelination have not been completely defined. It has been suggested that BDV has a specific affinity for oligodendrocytes; however, evidence supporting this is lacking. There is strong evidence that the hypomyelination seen in the brain and spinal cord in BD may be due to lowered activity of oligodendrocytes associated with subnormal thyroxine production. In the tested lambs with BDV, there were significantly decreased concentrations of serum triiodothyronine and thyroxine, and many of the thyroid follicle cells contained BDV. As in many other tissues occupied by BDV in persistently infected animals, little cell death or associated inflammation was present. Further support for the hormonal theory of hypomyelinogenesis came on finding significantly lower concentrations of the thyroid hormone-dependent enzyme 2',3'-cyclic nucleotide-3'-phospho-diesterase (CNP) in oligodendrocytes from affected animals. CNP is normally found in oligodendrocytes and its activity, which is dependent on the presence of both thyroxine and growth hormone, increases with myelination. Work in congenitally hypothyroid mice and thyroidectomized rats has shown that growth hormone and thyroxine are necessary for normal myelination of nerve fibers.

Abnormalities in the fleece are commonly seen in fetuses following in utero infections with BDV. In smooth-coated ewes and nannies infected between 50 and 85 days of gestation, the fleece of the fetus may become hair-like and curly. The hairiness is associated with enlargement of primary follicles, increased size of fiber, increased proportion of fibers with a central medulla, and increased diameter of the medulla. Around 90 days of gestation, animals become immunocompetent to the virus, and infection at that time may result in only a diminished number of secondary follicles. The reduction has been suggested to be the result of reduced fetal nutrition because of placentitis. In pigmented breeds, there may be large patches of abnormally pigmented black or brown fleece, especially along the neck. Exactly why these changes are induced has not been determined. However, using immunofluorescence, BDV antigen has been demonstrated in skin follicles of fetuses infected at 45 days of gestation, starting at 40 days postinoculation and continuing in lambs up to 5 months of age.

Intrauterine growth retardation commonly occurs with BDV infection in goats and sheep and was reported to be of similar degree to that seen in fetal starvation, cardiac anomalies, and placentitis, except for lung and brain, which were more severely affected. Growth-arrest lines are commonly observed in the long bones of BDV-infected fetuses and lambs. Arthrogryposis and kyphoscoliosis occur infrequently in conjunction with hydranencephaly, cerebellar dysmorphogenesis, and hypoplasia in BDV-infected fetuses.

BDV infection in sheep and goats causes *placentitis* that is particularly evident when infection occurs during the first trimester of gestation. Early in the infection, multiple white 1–2 mm foci of necrosis appear in the caruncles at the base of the crypts. These may fuse into a continuous band of necrosis, which may become mineralized and infiltrated with connective tissue and a few macrophages, or the entire base of the caruncle may be infarcted, necrotic, and infiltrated with neutrophils. The lesion is believed to be associated with endothelial swelling and thrombosis of capillaries in the endometrium and adjacent caruncle. The trophoblast does not usually undergo necrosis but may atrophy.

When several kids or lambs show typical signs of BDV infection, definitive **diagnostic tests** can be selected with confidence. However, diagnosis may be difficult when BDV occurs only as reproductive failure with embryo or fetal death followed by absorption, abortion, or mummification. Frequently in goats, abortion may be the principal sign as the placentitis is severe and proceeds quickly. In aborted fetuses with congenital abnormalities, diagnosis requires the detection of the virus, virus-specific antigens, or fetal antibodies against the virus in cavity fluids. The cotyledons, or preferably the uterine caruncles, are the best source of virus. It is variably recovered from aborted fetuses and almost never from those that are mummified. While isolates are usually noncytopathic, viral antigen can be demonstrated by direct or indirect immunofluorescence, immunoperoxidase, or avidin-biotin techniques in cryostat sections of selected tissues from affected lambs or the caruncle following abortion.

Sheep have been reported to retain BVDV in the uterus from one estrus to the next and to produce persistently infected offspring when naturally bred or artificially inseminated by semen collected from PI rams.

Naturally occurring BVDV infections in pregnant sows have been reported to pass to the fetus, causing stillbirth and neonatal death similar to chronic swine fever. Piglets infected in utero can either carry the virus (without antibody), develop antibody later, or become clinically affected and develop intestinal lesions depending on the stage of gestation when infection occurs. On necropsy, infected piglets may also have nonsuppurative meningitis and choroiditis. Swine fetuses dying early in gestation from in utero infections with BVDV may also be absorbed.

Equine arteritis virus infections of the pregnant uterus in mares

Equine viral arteritis (EVA) is a disease of horses caused by *Equine arteritis virus* (EAV), family Arteriviridae, genus *Arterivirus*. Genetic diversity of the virus is generated in the course of persistent infection of the carrier stallion and the genetic changes that maintain EVA in the stallion's reproductive tract likely affect phenotypic properties of the virus, such as virulence. Strains of the virus vary greatly in virulence. Consequences of infection range from subclinical to mild fever; ocular and nasal discharges; edema around the eyes, legs, and scrotum; skin rash; and, in severe forms, diarrhea, respiratory distress, and rarely death. Embryonic death and resorption rates are permanently increased, and 40–80% of pregnant animals abort or deliver a stillborn foal. Abortion usually occurs 1–4 weeks after the onset of fever, and is probably the most grievous manifestation of the disease, although in some outbreaks severe interstitial pneumonia and necrotizing enteritis may occur in foals.

The virus is spread by aerosolization of respiratory secretions among closely associated animals. *Stallions are probably the most important means of spread*, as they shed the organism in semen for a short or very long period, even for life, and transmit the disease sexually. There are minimal consequences of sexually acquired infection with little effects on conception rate, unless a mare is infected in the late stages of gestation, in which case she may abort. Stallions that are shedding the organism should not be used for breeding unless they are bred to seropositive mares that have received the organism from either vaccination or natural infection. In contrast, while mares may spread the virus during their illness or shortly after, they generally do not remain carriers and after recovery neither mares nor stallions shed the virus in nasal passage secretions, urine, or blood. Most horses develop a long-term immunity to EAV after natural infection of the virus.

Aborted fetuses are usually well preserved, but gross and microscopic lesions are rarely observed as the virus seldom produces active infection in the fetus. In foals surviving for more than 24 hours, fever, leukopenia, and/or thrombocytopenia are sometimes observed. Widespread inflammatory lesions in sections of the brain, liver, and spleen have been recorded. On microscopic examination, findings include interstitial pneumonia, lymphocytic periarteritis with fibrinoid necrosis of the tunica media, and renal tubular necrosis. Moderate arteritis with necrosis and mononuclear cell infiltrate has been reported in the myocardium of a few fetuses. In the uterus of the mare, however, there may be acute multifocal necrotizing myometritis associated with replication of the virus in smooth-muscle cells. Uterine infection might be the critical process contributing to abortion.

In the live mare and stallion during the early stages of disease, the presence of EAV may be determined by culture or polymerase chain reaction assay of swabs taken from nasopharynx and conjunctiva, from white blood cells, or from semen. The virus may be recovered from semen or revealed by breeding unexposed mares, which may then develop a fever or become clinically ill. Serological tests are available to detect previously infected animals. Samples for culture from the conceptus should include placenta, lung, and spleen. Diagnosis can also be obtained by immunohistochemistry combined with virus isolation.

Wesselsbron virus infections of the pregnant uterus in sheep and cattle

Wesselsbron virus (WESSV) is in the family Flaviviridae, genus *Flavivirus*, in the yellow-fever virus group. It is spread primarily by mosquitoes. Infection is often fatal in the ovine and bovine fetus, in newborn lambs and pregnant sheep. It may also produce congenital anomalies in bovine and ovine fetuses. Human illness is not fatal and is characterized by fever, chills, muscle pain, hyperesthesia, and a skin rash. Information is largely incomplete with regard to the pathogenesis and pathology of this infection in pregnant animals.

The disease is widespread in the southern and western parts of Africa in sheep and cattle; however, in spite of a high prevalence and high annual infection rate, mortality is low. In a naive flock of sheep, however, mortality in newborn lambs and pregnant ewes may be high. Pregnant ewes may die before or after abortion, whereas nonpregnant ewes, wethers, and yearlings usually show no signs of illness. *Changes in the liver due to WESSV infection may precipitate acute copper toxicity*, thereby inflating the perceived mortality directly due to this virus.

Pregnant sheep infected with WESSV develop a fever associated with initial viremia, and often abort at this stage due to the systemic effects of the virus on the dam. Under these circumstances, neither virus nor antibody is detected in the fetus. If the ewe does not abort during the primary viremia, the virus can invade the placenta and fetus in association with a second growth phase and result in death of the fetus. The fetus may be absorbed, mummified, aborted, or carried to term and be delivered dead. The death rate for lambs infected in utero approaches 100%, and even those born alive die soon after. Both wild and attenuated strains of WESSV have been shown to cause nonsuppurative menigoencephalitis, hydranencephaly, arthrogryposis, and hydrops amnii in fetal sheep; however, this is probably infrequent under field conditions.

In pregnant cattle, WESSV probably only crosses the placenta and infects the fetus in a low percentage of animals, even in the face of prolonged maternal viremia. When the virus does infect the fetus, abortion may occur or the calf may be born weak and die shortly after. These calves have typical liver lesions and precolostral antibody to WESSV. However, virus may not be recovered. Many pregnant cows, even after prolonged viremia, give birth to normal live calves that show no serological or virological evidence of infection. In cattle, as described in sheep, certain strains of the virus occasionally produce nonsuppurative meningoencephalomyelitis, porencephaly, and cerebellar hypoplasia in the fetus.

Gross and microscopic descriptions of findings in aborted fetuses, or stillborn lambs and calves, are limited. Experimentally infected newborn lambs have a slight to moderately enlarged, yellow to orange, variably congested liver. On microscopic examination, hepatocyte necrosis is slight to extensive, but is usually single-cell and generalized. *Eosinophilic, intranuclear inclusion bodies of various shapes are frequently present*. Separated, individual hepatocytes may be round, shrunken, and have intensely pink-staining cytoplasm and nuclear lysis (Councilman bodies). Kupffer cell hyperplasia is prominent, particularly in the central vein region, and Kupffer cells filled with yellow or pink granular material often bulge into sinusoids. The sinusoids also contain large numbers of mononuclear cells and degenerating neutrophils. Bile ducts and canaliculi are frequently distended with bile. In portal areas, there is bile duct hyperplasia, moderate numbers of macrophages, and some neutrophils and plasma cells. There are petechial and ecchymotic hemorrhages on the mucosal surface of the abomasum and the content is dark brown. Other nonspecific lesions, consistent with a viremia, are also described.

The **diagnosis** *of WESSV infection in pregnant animals is based on clinical findings, histology, and culture from liver and brain*. The lesions produced by Rift Valley fever virus infection may easily be confused with Wesselsbron disease, and, although the liver lesions tend to be different, complications due to precipitation of copper toxicity may make the differentiation difficult.

Porcine parvovirus infections of the pregnant uterus

Porcine parvovirus (PPV) is in the family Parvoviridae, subfamily Parvovirinae, genus *Parvovirus*. *PPV is an important and common cause of reproductive failure in pigs, and manifests as embryonic death with reabsorption, mummification, stillbirths, and reduced litter size.* Farrow-to-finish farms are affected nearly twice as often as feeder pig farms, probably due to the maintenance of a continual reservoir of PPV in the finishing pigs. The virus is most commonly spread by the ingestion of contaminated feces, and will adhere to the zona pellucida of embryos. Viremia develops in susceptible pigs, and in pregnant pigs the virus enters the placenta and passes to the embryo or fetus 23–32 days following oral inoculation. Up to a fetal age of 70 days, the virus may cause death of the embryo (with absorption) or fetus (with mummification); however, the porcine fetus becomes increasingly resistant to the effects of the virus after 36 days and is immunocompetent by about 70 days. Death of the fetus may be due to the total effect of the virus on rapidly dividing cells, including neurons and capillary endothelium of the cortical laminae in cerebellum and cerebrum, and cells in the lung, liver, pancreas, and chorioallantois. Movement of virus from one fetus to another may be affected by development of maternal antibody, increasing resistance of fetuses with advancing age, and the variability of the circulation and contact between the placental membranes of adjacent fetuses.

When PPV is introduced by the uterine route, it causes inflammation in the ovaries and degeneration of uterine epithelium, both of which may contribute to reproductive failure but do not otherwise cause clinical signs. Uterine changes may include marked variation in surface epithelial cell height, epithelial cell basophilia, degeneration, and ulceration. Light infiltration of neutrophils, eosinophils, and lymphocytes may be present throughout the endometrium. Corpora lutea contain foci of mononuclear cells, many of which are lymphoplasmacytic. *In the fetus, lesions are most commonly observed in older fetuses and may be present in kidney, liver, brain, and fetal placenta.* In the cerebrum, which is the most dependable site, perivenous accumulations of adventitial cells, plasma cells, and other mononuclear cells occur in white and gray matter and in meninges. Similar accumulations are observed in the renal interstitium, hepatic portal regions, and in the chorioallantois.

For **diagnosis**, viral antigen is demonstrable by the fluorescent antibody test in affected tissues of embryos, mummified and stillborn fetuses, and a highly sensitive DNA probe, specific for PPV-infected cells, is available. *Identification of specific antibody, particularly IgM, in fetal fluids indicates fetal infection, and with other appropriate findings is supportive evidence for the cause of reproductive failure.* When the only manifestations are small litters or pigs that recycle, the causal relationship of these signs with PPV is difficult to establish, and knowledge of titers of antibody against PPV in the gilt or sow before and after the event may be the only incriminating evidence. Various tests, including an enzyme-linked immunosorbent assay, have been developed for this purpose.

Bovine parvovirus infections of the pregnant uterus in cattle

Bovine parvovirus (BPV) is in the family Parvoviridae, and is the type species for BPV-like viruses; it is widely distributed in cattle populations throughout the world. *It is reported to cause enteritis and diarrhea in young calves, and abortion and birth of weak calves when infections occur in naive pregnant cows. The organism is not considered a major cause of abortion*, but this may be because it is not looked for consistently in submissions. Anywhere from 10 to 100% of the cattle in a population will have antibody to parvovirus and work in the USA suggests that, when reproductive problems, including repeat breeding, embryonic mortality, and abortion are considered, animals with antibody to bovine parvovirus had about three times as many of these problems as compared to control seronegative animals.

Bovine parvovirus is excreted in the feces of affected and normal animals, and the oral route may be important in transmission. Inoculation of parvovirus into pregnant cows can cause in utero fetal death and abortion in the early stages of gestation. Some calves may be born with cerebellar hypoplasia due to lysis associated with the multiplication of BPV in cells of the external granular layer. Cerebellar hypoplasia is believed to follow infection occurring in the period of rapid cell multiplication (107–150 days' gestation) in the cerebellum. *Cowdry type A inclusions* are seen in external granular cells, hepatocytes, adrenal cortical cells, and intestinal crypt cells associated with areas of necrosis. Bovine fetuses are capable of forming IgM antibody to the virus by 93 days' gestation; infections in the third trimester usually only result in antibody formation with no abortion.

For **diagnosis**, BPV may be recovered in a variety of tissues, including placenta, amniotic fluid, adrenal glands, and liver. When infection occurs in mid-gestation, detection of specific antibody in fetal serum may be used as putative evidence of the cause of abortion. The presence of antibody may interfere with recovery of the virus but probably will not completely prevent isolation, as the virus is frequently cell-associated.

Canine minute virus

Canine minute virus (CMV) is a species distinct from *Canine parvovirus 2* and *Feline panleukopenia virus* in the genus *Parvovirus*, and antibody to it is widespread among dogs. It may occasionally cause mild diarrhea in pups, but its significance is poorly defined. Experimental oral–nasal infection is clinically inapparent, but it may produce inclusion bodies in the cells of the duodenal crypts. Transient lymphocytolysis in the cortex of lymph nodes, thymus, and in gut-associated lymphoid tissue has been reported.

The virus seems capable of transplacental transmission to the fetus, and exposure of pregnant dogs has been associated with fetal resorption, or birth of dead or weak pups, depending on gestational stage at exposure. Anasarca and myocarditis are reported in dead or weak puppies. Spontaneous reproductive failure associated with MVC is not reported.

The *pathogenesis* of MVC and its clinical significance are not yet known, but preliminary findings suggest it may be responsible for a portion of deaths in pups less than 4 weeks of age and it may cause reproductive failure. Virus isolation is difficult, possibly because of antibodies in infected dams at the time they resorb their fetuses; however, histological examination of tissues from dead pups may reveal viral inclusion bodies in small intestinal villus epithelial cells or bronchial epithelial cells. Much more information is necessary to ascertain the role of this virus in canine disease. *Reports of deaths and abortions suggest it is more common than currently recognized.*

Diagnosis can be confirmed by immunofluorescence or immunohistochemistry.

Bluetongue virus infections of pregnant sheep and cattle

Bluetongue virus (BTV) is a nearly worldwide viral infection of sheep and other ruminants. In sheep and, with much less severity and frequency, in cattle, the disease is characterized by fever, erosive to ulcerative lesions of the upper gastrointestinal mucosa, and focal hemorrhage and necrosis of smooth, skeletal, and cardiac muscles. BTV infections are rarely fatal; and in cattle, most infections are subclinical. *Infections occurring during pregnancy, however, can cause heavy losses due to early in utero death and absorption, abortion, mummification, or stillbirth with severe fetal growth retardation and multiple congenital anomalies.*

BTV is a member of the family Reoviridae and is the prototype virus for the genus *Orbivirus*. There are several serotypes of BTV, and they vary greatly in virulence. The virus is mainly spread by, and can multiply in, various species of biting gnats in the genus *Culicoides*. With many serotypes of BTV, viremia exists for a longer period in cattle than in sheep, and in both, antibody and virus may coexist for several days. The prolonged viremia seen in cattle has led some investigators to designate them as the reservoir host for this virus. The virus has been found in the semen of a few bulls; however, it is usually transient and therefore of less importance than arthropods in transmission.

When an animal becomes infected, primary virus replication occurs in the lymph nodes draining the site of inoculation. This is followed by extension through the lymphatics and bloodstream to the spleen and other lymph nodes, where the virus propagates and is carried via the blood to a variety of tissues. The organism appears to be closely associated with erythrocytes during viremia. Species-specific differences in the production and activities of endothelial cell-derived inflammatory and vasoactive mediators appear to contribute to the greater sensitivity of sheep than cattle to BTV-induced microvascular injury.

The consequences of infection during pregnancy depend on the stage of gestation when infection occurs and on the serotype of virus. Infections in sheep up to approximately 50 days of pregnancy may result in death of the conceptus and absorption or abortion. Between 50 and 80 days of gestation, *necrotizing encephalopathy* occurs; and in the last third of gestation, as immunocompetence increases, there may be no obvious disease. On the other hand, infections of near-term and newborn lambs can result in a sluggish immune response, possibly associated with the rise in fetal cortisol at parturition and the ingestion of colostrum, both of which may suppress the active immune response.

Lesions in the brain of the *ovine fetus* infected during the 50–70-day period consist of diffuse infiltration of mononuclear cells in the meninges and necrosis of the cerebral cortex. The meninges and areas of necrosis gradually become infiltrated with macrophages and, unless the fetus is expelled early, appear as variably sized fluid-filled cavities (porencephaly and hydranencephaly), frequently accompanied by some degree of hydrocephalus in the new or stillborn lamb. Cerebellar dysgenesis, retarded development, and skeletal growth-retardation lines have also been described in fetuses inoculated with BTV. The lungs in fetuses inoculated with virus at 80–100 days become infiltrated with large mononuclear cells within the interstitium of small arterioles. These accumulations eventually form continuous overlapping nodules of large mononuclear cells that have abundant cytoplasm and indented nuclei. Similar lesions are occasionally seen in the renal medulla and hepatic portal areas. Cortical regions of lymph nodes are enlarged by large numbers of primary and secondary lymphoid follicles that contain numerous plasma cells. In the spleen, small white nodules are visible on the cut surface. These consist of greatly expanded periarteriolar lymphoid tissue.

Lesions in the *bovine fetus* develop similarly, and up to 70 days of gestation, BTV infection may result in in utero death and absorption or abortion of the conceptus. Between 70 and 130 days of gestation, serotypes 10, 11, 13, and 17 can cause hydranencephaly and death of the fetus. Two distinct processes may be involved in the development of central nervous system lesions due to BTV infections in bovine fetuses: *infarction*, associated with viral-induced vascular injury, is probably responsible for the large areas of necrosis and cavitation occurring in the rostral regions of the cerebrum; whereas *viral destruction* of clusters of individual cells, including glial cell precursors, results in foci of necrosis and accounts for microcavitation. Collapse of these cavities may facilitate dilation of the lateral ventricles and subsequent hydrocephalus. Death of calves with hydranencephaly pre-empts them spreading the virus by an arthropod vector, even if they are viremic. The earliest evidence of antibody activity against BTV group antigen in bovine fetuses occurs at around 145 days of gestation; by 200 days, there is significant neutralizing antibody activity, therefore no virus is detectable at birth.

Diagnosis of in utero infections in cattle and sheep is based on finding the typical lesions and specific fetal antibody to BTV in cavity fluid or blood. Virus isolation after fetal immunocompetence to BTV is unlikely but not invariable. Maternal precipitating antibody (agar gel immunodiffusion test) may be absent at term, while neutralizing antibody may be more persistent. The c-enzyme-linked immunosorbent assay for specific neutralizing antibody is more specific and sensitive. To culture the virus from blood, animal inoculation or washed erythrocytes may need to be used because the organism is closely associated with red cells. BTV and EHDV can be detected and differentiated by multiplex RT-PCR.

Epizootic hemorrhagic disease virus infections of the pregnant uterus in cattle, sheep, and white-tailed deer

Epizootic hemorrhagic disease virus (EHDV) is an arthropod-borne virus in the family Reoviridae, genus *Orbivirus*. It exists as at least two serotypes, 1 and 2, and is present in Africa, Australia, North America, and Japan. *Ibaraki disease virus*, first isolated in Japan, is a serotype-2 strain. EHDV is spread by *Culicoides* spp., and *causes fatal hemorrhagic disease of white-tailed deer.* In cattle, the Ibaraki strain can cause severe ulceration of the mucosa of the mouth, tongue and esophagus with necrosis of esophageal musculature and marked pain on swallowing. Many animals die. In many respects the disease is similar to BTV infection in sheep, but, in contrast to BTV, *EHDV has very low pathogenicity for sheep.* Although EHDV cross-reacts with BTV in some serological tests, it is considered to represent a separate population of viruses. Experimental inoculation of BTV has been reported to cause abortion and mummification in white-tailed deer. Because of its similarity to BTV, EHDV is also believed to be a cause of abortion and congenital anomalies in cattle, but this has not been proven.

Chuzan disease of cattle

Chuzan virus (CHUV, syn. *Palyam virus*) has been isolated from cattle and the midge *Culicoides oxystoma*. The virus is in the family Reoviridae, genus *Orbivirus*, Palyam serogroup, and is most closely related to *African horsesickness virus* within the orbiviruses. CHUV has been incriminated as the cause of an epizootic in the Kyushu district of Japan, wherein 2463 calves, mostly beef, were affected. A high percentage of newborn calves were born with *hydranencephaly and cerebellar hypoplasia.* A subsequent seroepidemiological investigation revealed evidence to suggest the organism had been spread from the most southerly island of Japan to the mainland in the north. Cattle in the region did not have antibody to the virus previous to this epizootic.

Calves involved in the epizootic were born alive and were normal in size and weight. Clinical signs and congenital abnormalities included corneal opacity, blindness, nystagmus, cerebellar ataxia, tremor, and opisthotonos. Necropsy lesions included hydranencephaly, hydrocephalus, microcephaly, and cerebellar hypoplasia. No lesions were seen in other organs and no virus was isolated from any of the calves; however, 44 of 49 precolostral serum samples checked for neutralizing antibody to CHUV were positive. Experimental infection of 15 cows at 89–150 days' gestation resulted in 14 normal calves and one calf with severe hydranencephaly and cerebellar hypoplasia.

For **diagnosis**, CHUV can be recovered from blood for up to 56 days after inoculation. It is closely associated with red blood cells, even in the presence of antibody. Demonstration of specific antibody in the serum of precolostral calves will be incriminating.

Canid herpesvirus infection in pups and pregnant bitches

Canine herpesvirus (*Canid herpesvirus 1*, CaHV-1), family Herpesviridae, subfamily Alphaherpesvirinae, is in the genus *Varicellovirus*. In adults or weaned puppies, CaHV-1 may produce mild upper respiratory infection, and inapparent infections are common. Infection of the neonate is possible by various routes. It may be transmitted from maternal lesions of genital herpes to the pup as it traverses the birth canal, from initial maternal infection, or by recrudescence of existing latent virus. Viral recrudescence can be induced in recovered animals by corticosteroids. There is considerable homology between endonuclease fragments of CaHV-1 and *Felid herpesvirus 1*.

Canine herpesvirus infection is regularly fatal for newborn puppies. Resistance to the disease is sharply age-related; pups exposed after 2 weeks of age will not develop severe illness. The disease has an incubation period of 3–7 days, after which the affected puppies rapidly sicken and die, usually within 2 days. The clinical signs lack specificity. Affected animals are not usually febrile; most vomit and refuse food. Their breathing becomes shallow and rapid, and shortly before death, the pups give evidence of abdominal pain.

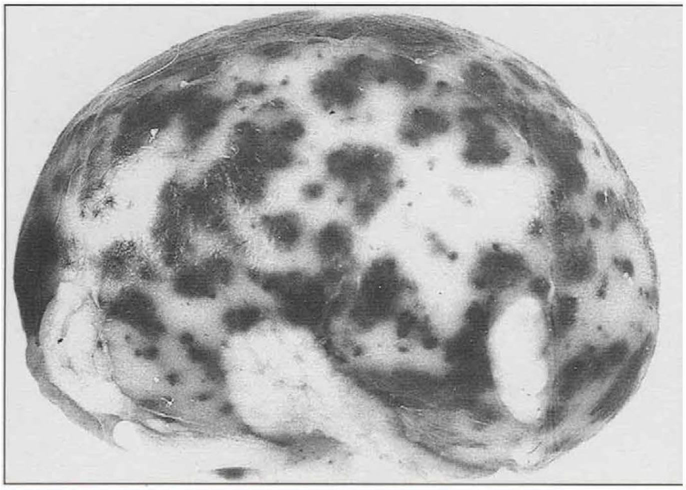

Figure 4.128 Renal hemorrhages in newborn pup due to *Canine herpesvirus* infection.

At autopsy, there is usually pleural and peritoneal effusion that may be blood-tinged. *Petechial and ecchymotic hemorrhages* are scattered throughout the subserosal tissue, usually representing the most impressive gross feature of the disease. Large hemorrhages are regularly seen in the kidney (Fig. 4.128). The lungs are wet, and frothy fluid fills the bronchi and bronchioles. Lymph nodes are enlarged and reddened, and splenomegaly is present. Tiny red foci, determined microscopically to be foci of necrosis, are occasionally seen in the liver. *Foci of necrosis are characteristic of the disease and may occur in any organ* (Fig. 4.129). Lung, heart, kidney, intestine, pancreas, adrenal, and spleen are common sites. The inflammatory response associated with these disseminated focal areas of necrosis is slight or absent. Viral inclusion bodies are not numerous, but can best be seen adjacent to the areas of necrosis in the liver or lung, or in the renal glomeruli. The inclusion bodies are intranuclear; most are basophilic, but some are faintly acidophilic.

Discrete microscopic lesions are present in the brains of the pup as early as 72 hours after experimental infection. These increase in severity as the disease progresses. They consist of nonsuppurative meningoencephalomyelitis, characterized by destruction of gray

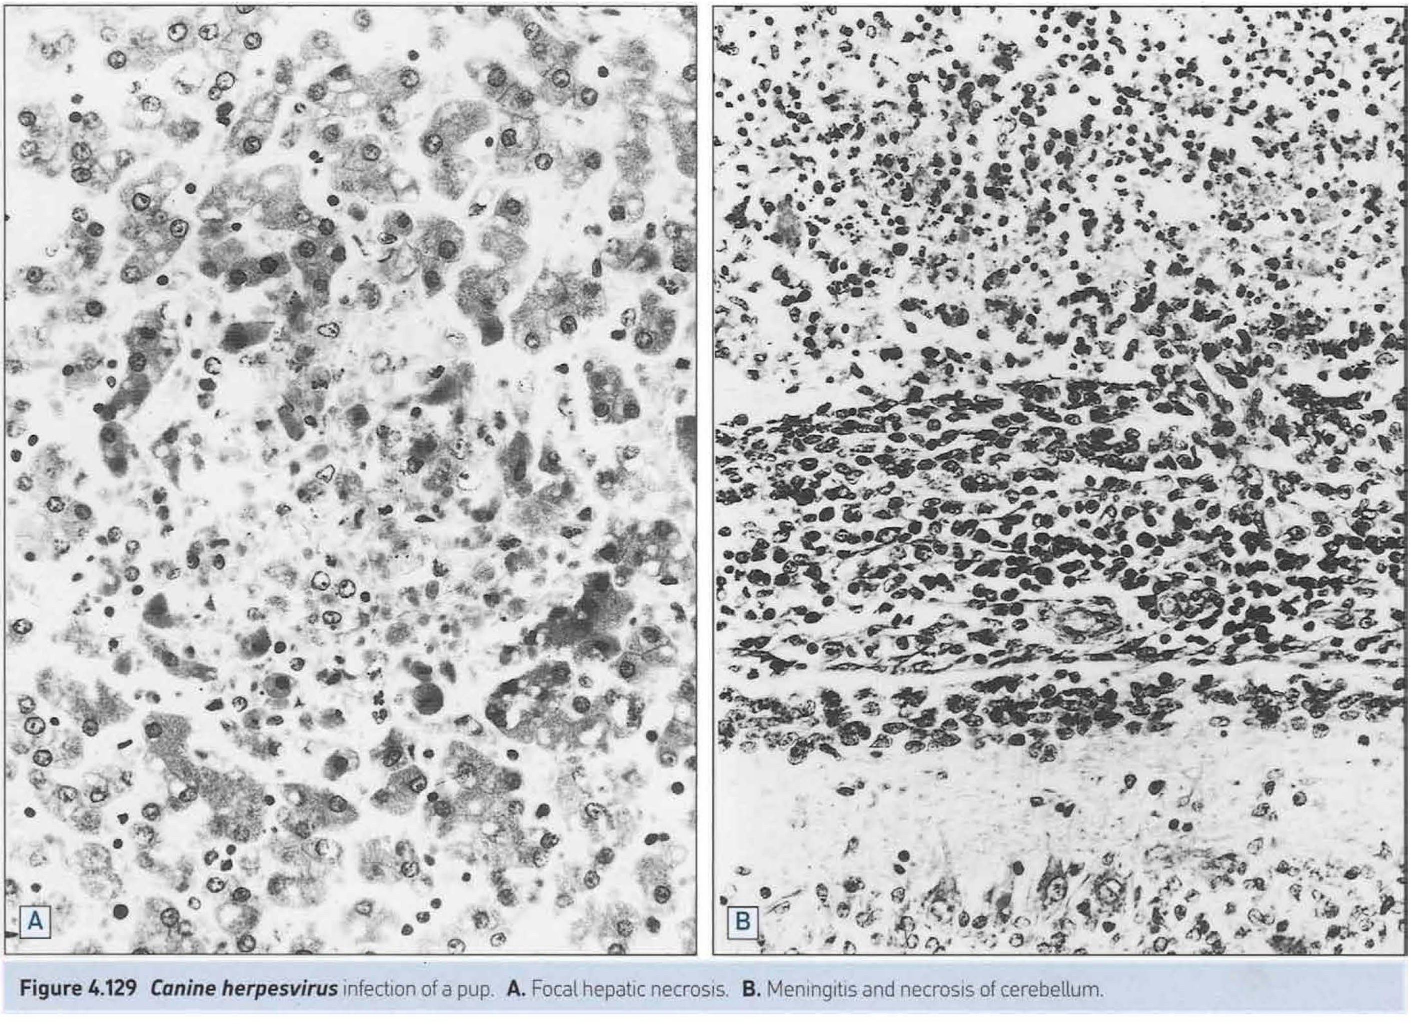

Figure 4.129 ***Canine herpesvirus*** infection of a pup. **A.** Focal hepatic necrosis. **B.** Meningitis and necrosis of cerebellum.

and white matter; the gray is somewhat more severely involved. There are focal and segmental areas of destruction of the cerebral cortices with concurrent microgliosis. Vascular changes vary from endothelial swelling to mononuclear cuffing. Diffuse pial meningitis with infiltrates of mononuclear cells and neutrophils is frequent, as is ganglioneuritis of the Gasserian ganglia.

Canine herpesvirus has been associated with abortion, stillbirth, and infertility. Depending on the time of gestation, inoculation of bitches with CaHV-1 has been reported to result in death and expulsion of fetuses, mummification, or premature delivery of live puppies. Focal areas of necrosis with intranuclear inclusions were variably observed in liver, spleen, kidney, placental labyrinth, and heart. Endothelium and trophoblast were commonly involved. Virus was recovered from many of the fetuses.

Suid herpesvirus 1 infections causing abortion in swine

Suid herpesvirus 1 (SuHV-1, Pseudorabies virus, Aujeszky's disease virus) is in subfamily Alphaherpesvirinae, genus *Varicellovirus. SuHV-1 is capable of causing reduced fertility in boars and sows, fetal resorption, mummification, abortion, and stillbirth in sows, and fatal meningoencephalitis in young pigs, sheep, cattle, and dogs.* Strains of SuHV-1 vary in their ability to invade the placenta and fetus; however, abortion without invasion of the conceptus may occur secondary to fever and nervous disease in the sow. When the virus does invade the placenta and fetus, characteristic gross and microscopic lesions are produced. There is a strong correlation between the ability of strains to cause syncytial formation in cell culture and their ability to produce disease in pigs and cattle.

The disease has a worldwide distribution, and the carrier sow is the most important source of the virus. Recrudescence and shedding through nasal mucus may occur following stress, and there is some evidence for long-distance airborne transmission, although this would appear not to be a major threat. Boars may carry SuHV-1, spreading it through nasal mucus and semen. The virus can survive in a pen for up to 2 weeks.

The virus enters the nasal passages of the susceptible pig and passes via the pharyngeal and olfactory nerves to the brain, where it rapidly spreads to the rest of the brain, causing nonsuppurative meningoencephalitis. It has affinity for the respiratory tract, and may induce severe rhinitis, tonsillitis, and pneumonia.

Abortion usually occurs about 10 days after the onset of clinical illness in the sow. If the placenta and fetus are invaded, lesions consist of multifocal coagulative necrosis of chorionic villi and focal coagulative necrosis in many organs, including liver, adrenal, and spleen. *Intranuclear inclusions* have been observed in trophoblast and interstitial cells and hepatocytes around areas of necrosis.

Virus may be demonstrated in nasal or vaginal swabs and fetal tissues by isolation and fluorescent antibody or enzyme-linked immunosorbent assays; polymerase chain reaction assays are also available.

Suid herpesvirus 2 (cytomegalovirus) infections of the pregnant uterus of the pig

Suid herpesvirus 2 (SuHV-2, Swine cytomegalovirus) is in the family Herpesviridae, unassigned to a subfamily or genus. Infection by this virus is normally confined to pigs, and was first described in England in 1955 as *inclusion body rhinitis* and, subsequently, as a transplacental infection of fetal pigs, in 1961 in Australia.

In neonates, SuHV-2 causes *mild to severe nonsuppurative necrotizing rhinitis* characterized by the presence of *large basophilic intranuclear inclusions* in the epithelium of the mucous glands and ducts in the nasal mucosa. The virus usually affects young pigs (less than 4 weeks old) but in naive herds may cause death in pigs of 4–12 weeks. The virus occasionally causes severe systemic disease in mature pigs. *When infection occurs in pregnant sows, they may deliver small litters, mummified fetuses, or stillborn or weak piglets either before or on the due date.* Pigs infected in utero may be born alive, small-for-gestational-age, and may develop systemic signs and die. Subsequent reproductive performance in infected sows may be reduced and manifested as decreased conception rates and decreased litter size.

Surveys of pig herds for serum antibody to SuHV-2 indicate infection to be widespread throughout the USA, Canada, Europe, Australia, and New Zealand. Transmission occurs when newly infected pigs excrete the virus in nasal and ocular secretions and urine. Boars may also excrete it in semen, and sows in cervical discharges. The virus has the capacity to remain latent in macrophages and other cells of the monocyte–macrophage system. Animals with latent virus may also excrete it, even in the face of serum antibody, following administration of corticosteroid and probably following periods of stress. Heavy losses are infrequent in commercial herds; however, in gnotobiotic pigs or minimal-disease herds in which pigs have had no previous experience with the virus, the introduction of actively or latently infected animals may prove disastrous.

When a sow is infected with SuHV-2, multiplication occurs first in the nasal mucosa. This is followed by viremia and dissemination of virus to many body organs, including the placenta in pregnant sows. The virus seems to pass through the placenta without inducing injury; experimentally the virus has not been isolated from the placenta, even when the fetus that has just died is positive. Neither has antibody been detected in piglets that become infected in utero. Fetuses die 4–6 weeks after inoculation of the sow, and the time is independent of the stage of gestation. Casualties of infection are scattered randomly throughout the uterus in various stages of decomposition and mummification, much as with porcine parvovirus infection. Following experimental infection, no gross lesions were seen on necropsy of the autolysed fetuses. However, on microscopic examination there was cytomegaly, and intranuclear inclusions were observed in liver and lung. In a natural outbreak of SuHV-2 infection, pigs born alive with a congenital SuHV-2 infection usually died within a week. Gross lesions in these consisted of pulmonary edema and congestion, hydrothorax and hydropericardium, and multiple firm, gray foci in the most ventral portions of the lungs. Mediastinal lymph nodes were enlarged and petechial hemorrhages were visible on the heart, lungs, intestine, and kidneys. Histologically, there was pulmonary edema and hemorrhage; alveolar septa were thickened, mainly by macrophages, but lymphocytes and neutrophils were also present. Large basophilic intranuclear inclusions were present in capillary endothelial cells and macrophages. Similar inclusions were present in capillaries of the renal medulla and tubular epithelium. Two types of inclusion have been observed: the usual large basophilic type found in pulmonary macrophages and glands and ducts of the nasal mucosa and renal tubular epithelium, and a small herpesvirus-like inclusion found mainly in monocyte–macrophage cells. Nonsuppurative meningoencephalitis has been reported in some pigs and was characterized by perivascular lymphocytic infiltrates and gliosis in the choroid plexus and vessels outside the cerebral cortex.

Experimental infections of piglets in utero or newborns less than 2 weeks of age have shown them to be very susceptible and to develop severe debilitating disease, with death a common sequel. This severe infection has been related to viral infection in the cells of the monocyte–macrophage system. This results in disseminated hemorrhage and edema in the lung, kidney, adrenal, liver, and lymph nodes, all of which is associated with viral destruction of macrophages and capillary endothelial cells. In the less severe and nonfatal forms of the disease, there is invasion of the mucus-producing cells of the nasal mucosa, the cells of the renal tubules and, less frequently, the epithelium of the salivary glands, Harderian and lacrimal glands, seminiferous epithelium, epithelium of ductus epididymis, mucous glands of the esophagus, duodenum, jejunum, and hepatocytes. Invasion of macrophages and endothelium or epithelium is not completely exclusive and both occur often.

The cytomegalovirus inclusions seen on histology when correlated with appropriate signs are **diagnostic** *of SuHV-2 infection in pigs.* Infection in a herd may be revealed by detecting antibody in the maternal serum using an indirect immunofluorescent (IIF) antibody test on infected lung macrophages. To detect virus, samples of nasal mucosa, lung, and kidney can be cultured directly on lung macrophages. Viral antigen may be detected in frozen sections of affected lung or kidney using the IIF test. As stated previously, the organism is not found or seen in the placenta, and antibody is not present in the fetus but may be present in piglets infected after birth.

Bovine herpesvirus 1 infections of the pregnant uterus in cattle, goats, sheep, and pigs

Bovine herpesviruses cause a wide variety of diseases in several species, including cattle, sheep, goats, wildebeest, and other wild ruminants. They are divided into six different groups, designated BoHV-1 to BoHV-6. The infections of the pregnant uterus caused by bovine herpesviruses that will be discussed in this section include BoHV-1 (infectious bovine rhinotracheitis virus, IBRV; infectious pustular vulvovaginitis virus, IPVV), and BoHV-4 (Movar virus, a cytomegalovirus).

Bovine herpesvirus 1 is in the family Herpesviridae, subfamily Alphaherpesvirinae, genus *Varicellovirus*. Based on restriction endonuclease analysis and cross-hybridization, BoHV-1 is subdivided into three antigenic variants or subgroups: subgroup 1 – IBRV; subgroup 2 – IPVV; and subgroup 3 – neuropathogenic. *IBRV and IPVV both cause abortion. IBRV is considered to be more virulent than IPVV* and, in addition to abortion, causes severe upper respiratory disease, endometritis, oophoritis, mastitis, dermatitis, and fatal diarrhea of young calves. IPVV primarily causes inflammation of the penis and sheath in bulls, inflammation in the vagina and vulva in cows, and abortion in cows.

BoHV-1 is distributed worldwide. Cattle-to-cattle transmission is the principal method of spread, and virus is easily dispatched from naturally infected or vaccinated cattle to susceptible animals through respiratory, ocular, or vaginal discharges. *All BoHV-1 strains*, including thermosensitive and thymidine kinase-negative strains, *are capable of becoming latent* and therefore undergoing recrudescence and shedding from mucous membranes. Virus is more abundant in excretions from primary than from recrudescent infections; however, transmission may occur from either. Live vaccine viruses may become latent and none of the vaccines can prevent latency by a superinfecting challenge virus, but, if the antibody titer is high in the vaccinate, the incidence of latent superinfection and amount of virus excreted may be lowered. Recrudescence may be induced by superinfections, corticosteroids, transport, parturition, and other stressful situations. Semen may also be an important source of the virus and embryo transfer fluids less so.

Sheep, goats, and pigs often have antibody titers to BoHV-1 and may occasionally show clinical signs of disease. Infection may manifest as an upper respiratory disease, which usually goes unnoticed; however, sheep may develop pneumonia. Abortions, from which BoHV-1 has been recovered, have been described in sheep and pigs. Sheep, goats, pigs, and wild ruminants are rarely the source of BoHV-1 virus for other animals; it is more likely that cattle transmit the virus to them, and disease is an infrequent event.

When the virus enters the mucosa of the respiratory or genital tract in pregnant animals, it multiplies at that site and is carried to the rest of the body in infected leukocytes and blood to the uterus. It has been postulated that, on reaching the caruncle, the virus passes

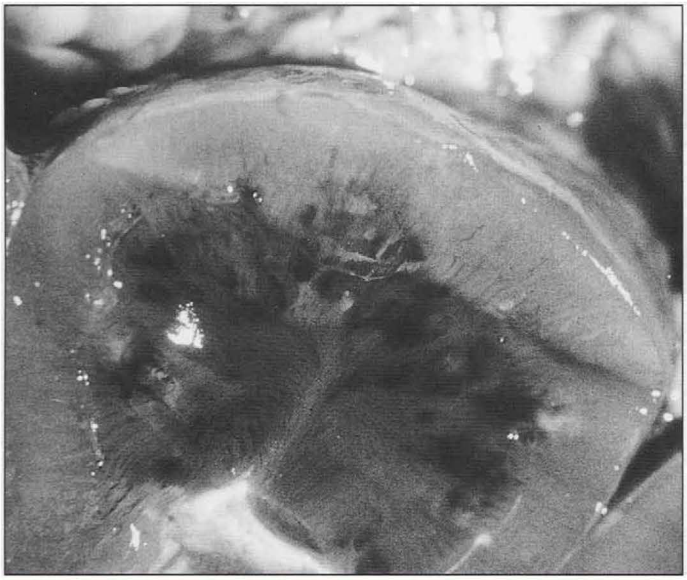

Figure 4.130 Focal renal hemorrhage and necrosis due to *Bovine herpesvirus 1* infection in a day-old calf.

though the trophoblast to the interstitium of the villus, therein infecting endothelium, mesenchyme, and then trophoblast. Death is due to tissue destruction in the fetus and the placenta. Early hatched embryos are also susceptible to IBRV infection.

Abortion rates in a herd of cattle may reach 25%; however, the prevalence of abortion in a region declines with a reduction in the naive population. Most cows infected with BoHV-1 do not abort until 3–6 weeks following the initial infection, and a significantly greater number of cows abort between 5 and 8 months of gestation than earlier. It is speculated the virus can stay in the placenta for a prolonged period before invading the fetus. As the virus invades, the fetus dies quickly with no preparation for delivery. *Expulsion occurs 3–5 days following fetal death, and the carcass is in a state of advanced autolysis.* Rarely, fetal death coincides with the time of normal delivery and the fetus is discharged well preserved.

Gross lesions in the fetus are usually absent or masked by autolysis, but when visible include white to tan 1–3 mm diameter foci of necrosis under the liver capsule and, more rarely, on the surface of the lung. Perivascular renal hemorrhage may be present in addition to focal hemorrhages at the corticomedullary junction in the kidney (Fig. 4.130).

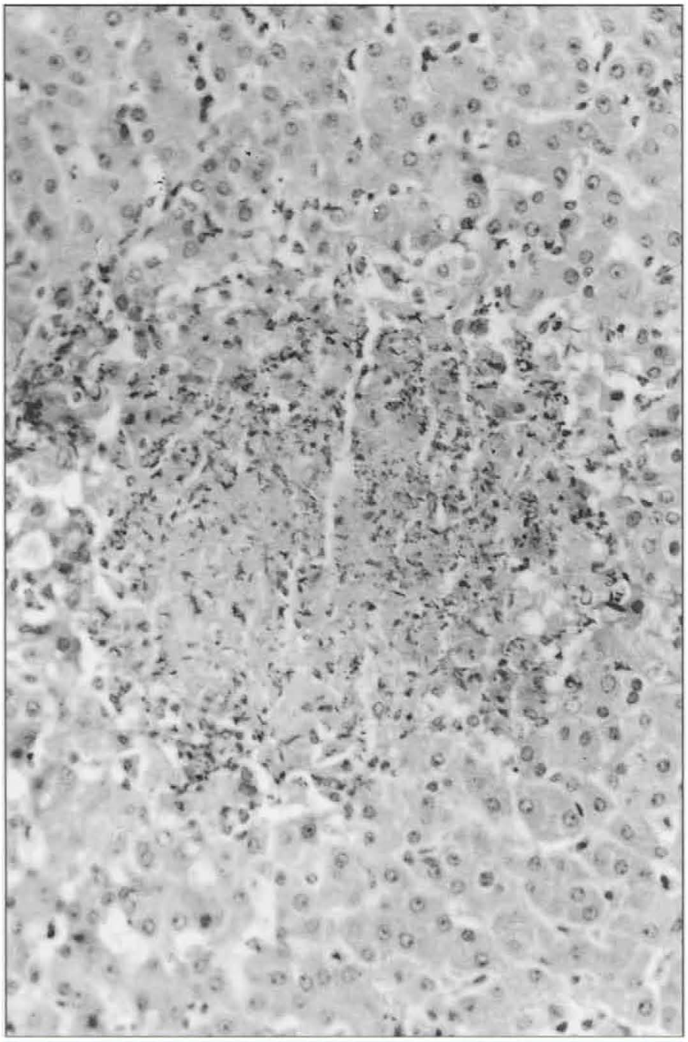

Figure 4.131 Focal hepatic necrosis due to *Bovine herpesvirus 1* infection.

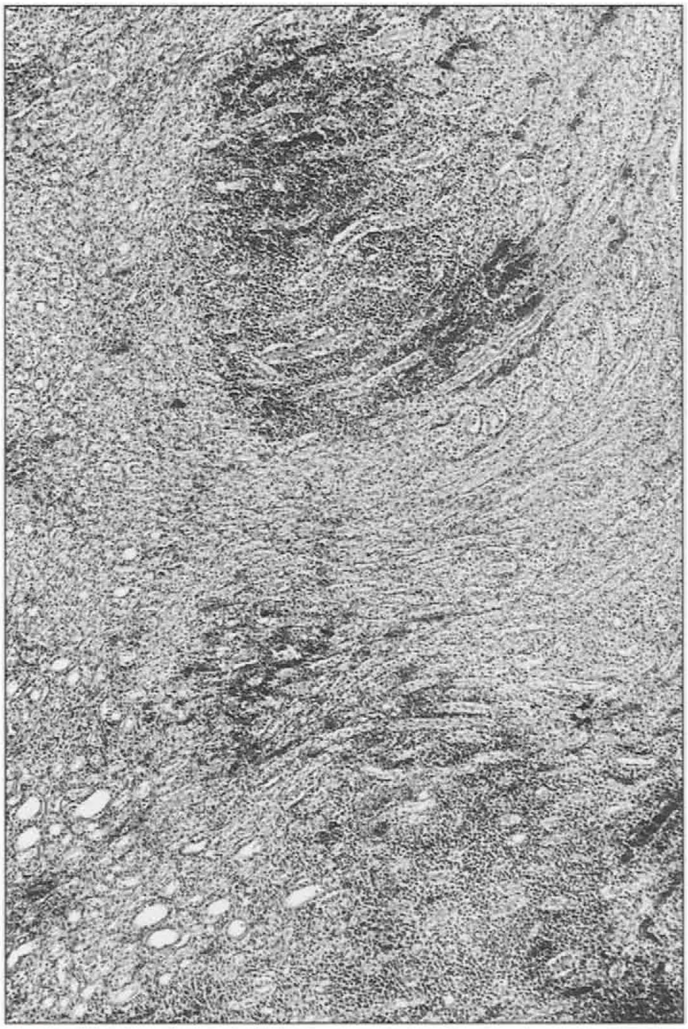

Figure 4.132 Renal necrosis due to *Bovine herpesvirus 1* infection in a day-old calf.

On microscopic examination, foci of necrosis with minimal cellular infiltrate can be seen in many tissues, including liver, adrenal, kidney, intestine, lymph node, lung, and spleen (Figs 4.131, 4.132). As autolysis advances, *inclusion bodies* are difficult to distinguish but are most profitably sought in the adrenal within the more normal cells surrounding a focus of necrosis. Necrotizing vasculitis is consistently present in the small vessels of placental villi (Fig. 4.133).

To confirm the **diagnosis**, the immunoperoxidase test using monoclonal antibodies for BoHV-1 antigen is specific, highly sensitive, can be done on fixed tissue sections, and requires no tissue cultures. Results are also available quickly. Fluorescent antibody techniques on frozen tissue sections of kidney, liver, or placenta, and tissue cultures of these samples can also be used for detection of virus. To identify antibodies to BoHV-1, the enzyme-linked immunosorbent assay has a higher validity in differentiating a negative from a positive sample than the serum neutralization test. With BoHV-1, cows abort such a long time after initial infection that most animals have very low titers to the virus at that time. On an individual basis, therefore, antibody titers are of little value in diagnosis. Also, as the fetus dies quickly, there is usually no evidence of fetal antibody production.

Bovine herpesvirus 4 (cytomegalovirus) infections of the pregnant uterus in cattle

Bovine herpesvirus 4 (BoHV-4, Bovine cytomegalovirus, Movar virus) is in the family Herpesviridae, subfamily Gammaherpesvirinae (cell-associated herpesviruses), genus *Rhadinovirus*. It has worldwide distribution in cattle and has been associated with a wide variety of clinical conditions, including pneumonia, enteritis, metritis, mammillitis, and the disease syndrome "epivag." Epivag is characterized by vaginitis, salpingitis, and oophoritis, or epididymitis.

BoHV-4 is considered an important cause of abortion in cattle; however, experimental evidence confirming a causal relationship is incomplete. The virus is less virulent than BoHV-1, and concurrent infections of BoHV-4 with other pathogens are frequent (up to 75%). It has been suggested that the virus is immunosuppressive and thereby intensifies the effects of other agents. BoHV-4 has been isolated along with bovine viral diarrhea virus and border disease virus from abortions, and with *Mycobacterium paratuberculosis* from animals with Johne's disease.

As the virus is carried within mononuclear blood cells, grows on mucosal surfaces, and is also considered a poor immunogen, it elicits a low level of neutralizing antibody that is also of low avidity. It is transmitted from cow to cow in oral and nasal secretions and, during viremia, is carried to the placenta, where it multiplies and invades the fetus. The virus may remain latent in mononuclear blood cells and in the trigeminal nerve ganglion. Recrudescence can be induced with dexamethasone. Herds tested for BoHV-4 antibodies vary greatly in the proportion of cattle with antibody to the virus.

Mummification and birth of weak pigs have also been reported in association with BoHV-4 infections in sows. Fetal pigs are capable of developing antibody to the virus by 74 days' gestation. Recrudescence induced by dexamethasone has been reported in sheep and pigs, with spread of virus to other animals.

Descriptions of the lesions seen in the aborted bovine fetus are limited to one report. No gross lesions were observed in the fetus, but on histological examination there was thickening of alveolar septa in the lungs, where many large intranuclear inclusions were observed in large alveolar cells. Similar inclusions were also seen in cells of bile duct epithelium, myocardium, spleen, and epithelium of renal tubules. The virus was not isolated from this animal, but the inclusions seen on light and electron microscopy were typical of cytomegaloviruses.

To confirm the **diagnosis**, fetal lung, liver, and kidney should be cultured for the virus, and fluorescent antibody techniques may also be used to demonstrate its presence. Neutralization tests are usually unsatisfactory for the detection of antibody as the virus elicits a low antibody response. The enzyme-linked immunosorbent assay and an indirect immunofluorescent test have been found to be more sensitive and may have value on a herd basis. Antibodies may also be detected in cavity fluid of aborted fetuses and are evidence at least of fetal infection. A nested duplex polymerase chain reaction assay has been used to detect BoHV-1 and BoHV-4 in lymph nodes and peripheral blood leukocytes.

Equid herpesvirus 1 abortion in horses

Equid herpesvirus 1 (EHV-1, Equine abortion virus) is in the family Herpesviridae, subfamily Alphaherpesvirinae, genus *Varicellovirus*. It is widespread throughout the world and causes respiratory, neurologic, and generalized neonatal disease, as well as abortion. The virus can be separated into two distinct subtypes (1 and 2) on the basis of restriction endonuclease cleavage of the viral DNA. Both subtypes cause respiratory disease, abortion, and neonatal disease. Subtype 1, however, causes a more severe (but less frequently encountered) respiratory disease than subtype 2, and is the more frequent isolate from aborted foals and neonatal disease. Also, it is probably the only type causing neurologic disease. Subtype 2 is commonly isolated from mild upper respiratory disease in horses and less so from abortion. Respiratory disease due to EHV-1 is common in some areas, whereas abortion is rare; this may be explained to some extent by the presence of a subtype less likely to produce abortion but capable of producing respiratory disease.

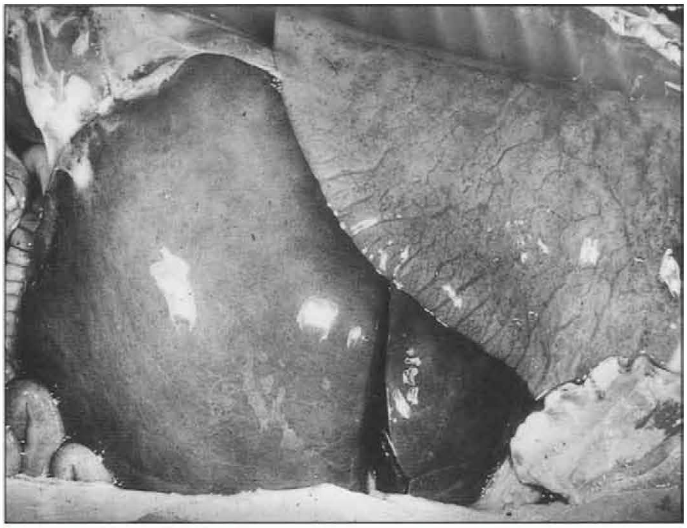

Figure 4.134 Pulmonary edema in an aborted equine fetus, due to *Equid herpesvirus 1* infection.

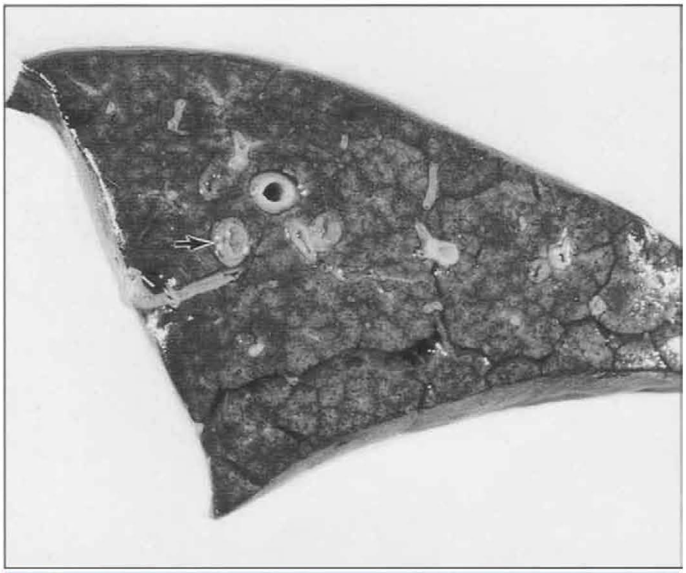

Figure 4.135 Fibrin casts in fetal bronchi, due to *Equid herpesvirus 1*.

EHV-1 is very widespread, and first exposure usually occurs before the foal is 1 year old. Mild-to-severe upper respiratory disease is produced, and secondary bacterial infection, frequently with *Streptococcus zooepidemicus* or other streptococci, is common. As the virus is so widespread and contact so likely at an early age, abortion usually occurs in an animal that has had previous experience with the virus. As with herpesviruses generally, the level of immunity is low, and the virus is transported in leukocytes through the bloodstream to the placenta and hence the fetus. Death of the fetus does not occur until the onset of the usually prompt and uncomplicated abortion. The dam shows no premonitory signs and the fetus is aborted in a fresh state. The time from exposure – whether by recrudescence of latent virus or reinfection – until abortion varies from 9 days to several months. Respiratory disease in the mare is usually not observed following the infection that results in abortion. It is reported that 95% of the abortions due to EHV-1 occur in the last 3 months of pregnancy, and naturally acquired infection has not been observed to produce abortion before 5 months of gestation. Exactly where the virus is, and in what state, during the protracted incubation period has not been determined.

The aborted fetuses may show *characteristic and diagnostic lesions* that are variable in their development and may be modest. Edema of the subcutis and fascia and accumulated amber fluid in the body cavities are common in aborted fetuses. There may be slight general icteric discoloration and meconium staining of the footpads and amnion. The most consistent gross lesion is *severe pulmonary edema*. The lungs are heavy and rubbery, show the impressions of the ribs, and exhibit a pitting response to pressure (Fig. 4.134). There is also edema of the interlobular septa. Their color may be darker or lighter than normal, and tan-to-white foci of necrosis (2–4 mm in diameter) and petechial hemorrhages may be visible on the surface. Casts

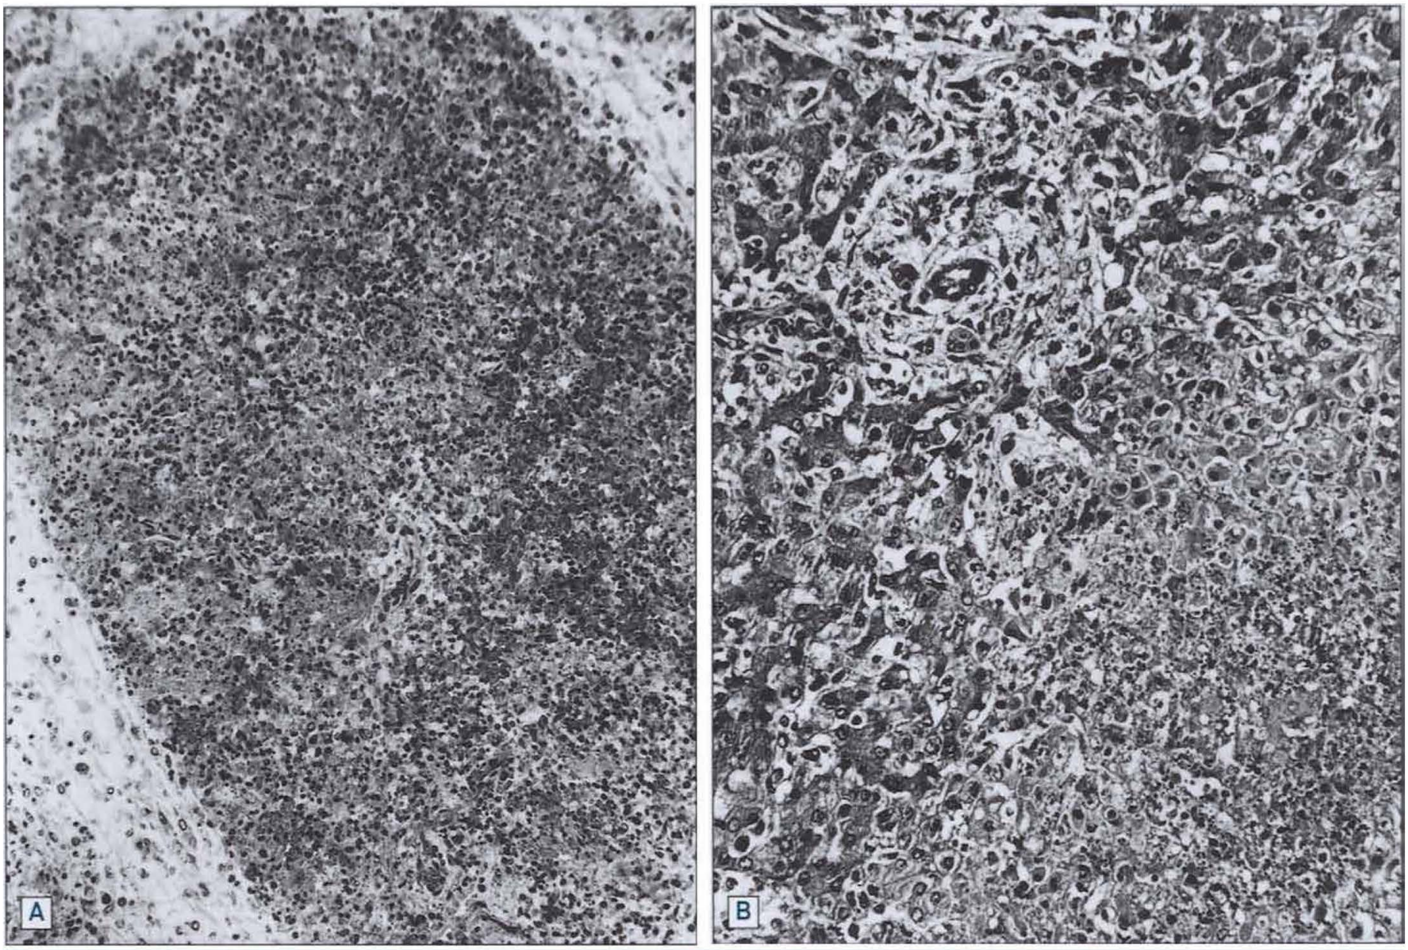

Figure 4.136 *Equid herpesvirus 1* abortion of an equine fetus. **A.** Acute necrotizing **pneumonia** in aborted equine fetus. **B.** Acute **hepatitis** with focal necrosis.

of fibrin are occasionally present in the bronchi (Fig. 4.135) and, rarely, in the trachea. Beneath the capsule of the liver there are, in about 50% of aborted fetuses, gray-to-white foci of necrosis varying in size from minute up to 5.0 mm in diameter. Such foci may be few or numerous. The spleen is usually enlarged, with petechial hemorrhages on the capsule and unusual prominence of the follicles on cut surface. Petechial or ecchymotic hemorrhages may occur anywhere, but chiefly in the upper respiratory mucosae. Occasionally, there is hemorrhagic necrosis of the renal cortices.

Histologically, the pulmonary interlobular septa are edematous and infiltrated with mononuclear inflammatory cells. The edema and spotty necrosis and hemorrhage involve the whole organ uniformly; there is fibrinous alveolar exudation and necrosis of bronchial and alveolar epithelial cells (Fig. 4.136A). *The acidophilic inclusion bodies found in the nuclei of the bronchial and alveolar epithelium are specific.* The foci of hepatic necrosis are not so common as the changes in the lungs: they are often minute and may be missed in a section. Acidophilic inclusion bodies also form in the nuclei of hepatic parenchymal cells, but they are not constant and are never numerous. If present, they can usually be found around the areas of focal necrosis. There is edema of the liver, and leukocytic infiltration in the necrotic foci and portal triads is common (Fig. 4.136B). Rarely, there is a diffuse hepatitis without focal necrosis. Necrosis of germinal centers occurs in the enlarged splenic follicles and other lymphocytic tissues, including thymus. Intranuclear inclusion bodies may be found in the primitive reticular cells in such foci. There are hemorrhages in the splenic pulp and about the malpighian corpuscles. The placenta is normal.

Foals infected with this virus in utero may be born alive at, or near, term. Whether any survive or not is not known. Many of them die in the first few days with severe interstitial pneumonia and secondary bacterial septicemia. Focal hepatic necroses are, as a rule, not present in these animals; however, focal necrosis of crypt epithelium with hemorrhage in the intestine is sometimes observed (Fig. 4.137).

The **diagnosis** of abortion can be made on observing typical microscopic lesions, including the presence of inclusions. The demonstration of EHV-1 on cell cultures from samples of lung, liver, spleen, or thymus or by the immunoperoxidase technique on placenta is definitive. Determination of the specific subtype may be accomplished using monoclonal antibodies. Serological examination for antibody is of little use in the diagnosis of abortion as most animals are exposed to the virus at several intervals in their life and abortion may occur too long after the last exposure, making interpretation impossible, even on the basis of paired samples.

Akabane virus infections of the pregnant uterus

Akabane virus (AKAV) is in the family Bunyaviridae, genus *Orthobunyavirus*, Simbu serogroup. In Australia, the Simbu serogroup includes Akabane, Tinaroo, Peaton, Aino, Douglas, Thimiri, and Facey's Paddock viruses; Akabane and Tinaroo viruses are naturally occurring reassortants. *Akabane disease*, commonly known as *enzootic bovine arthrogryposis and hydranencephaly* (ag/he), occurs in Australia, Japan, Korea, Israel, and Kenya. Evidence of disease in postnatal cattle, sheep, and goats is minimal; only slight leukopenia in goats and mild keratoconjunctivitis in cattle have been reported, plus one report of encephalomyelitis in cows. In contrast, infection of nonimmune pregnant sheep, goats, and cows has resulted in extensive losses in Japan, Israel, and Australia.

AKAV is transmitted by various insects, including the hematophagous midge *Culicoides brevitarsis* in Australia, and various species of mosquitoes, including *Aedes vexans, Culex tritaeniorhynchus,* and *C. pipiens*. Losses are seasonal and confined geographically by the range of the insect. Animals beyond this range constitute a naive population, and if for some reason infected insects invade this area, extensive losses may occur.

Infections by AKAV before 30 days in gestation can produce multiple congenital abnormalities and can result in normal or malformed fetuses that may be aborted, mummified, or delivered alive or stillborn, early, on due date, or late. Many are delivered with difficulty because of the congenital malformations. Anomalies observed include microcephaly, porencephaly, hydranencephaly, hydrocephalus, hydromyelia, arthrogryposis, kyphosis, lordosis, scoliosis, brachygnathia, and muscle atrophy. Additional abnormalities reported in lambs include spina bifida, cyclops, Arnold–Chiari syndrome, and anal atresia. When the fetus is infected between 41 and 50 days' gestation, thick perivascular cuffing of macrophages, lymphocytes, and plasma cells is observed, coupled with very prominent glial nodules. The large variety of central nervous system malformations caused by AKAV is attributed to differences in the fetal age at infection, the vulnerability of neurons to direct injury, and the nature of tissue response to such injury. Affected lambs are reported to weigh significantly less than normal lambs, even though gestation length overall is slightly extended. Infection of the fetus after 90 days' gestation is less severe; however, there are inflammatory lesions without malformation in the brainstem.

AKAV is carried by a midge or mosquito from a viremic to a susceptible animal, and at no time does the dam show clinical signs of infection. Viremia lasts for about 4 days, during which time the virus invades the placenta, replicates in trophoblastic cells, and finally crosses the placenta and infects the fetus. If AKAV is inoculated immediately after the integration of the placental cotyledon with the maternal caruncle, viral invasion of the chorioallantoic membrane occurs rapidly. Lesions in the brain and possibly in muscle are probably due to the direct cytopathic effect of the virus on developing neurons. A regular sequence of events follows the primary insult of polioencephalitis; focal necrosis in the brain may progress to malacia and, depending on the extent of the injury and time, to porencephaly and hydranencephaly. Neuronal death in brain and ventral spinal cord motor neurons is followed by neurogenic atrophy of muscle and arthrogryposis.

Necropsy findings in affected species are similar. *In the brain, gross lesions have a broad range, including microcephaly, hydrocephalus, porencephaly, and hydranencephaly.* Cystic cavities vary from being visible only microscopically to having almost complete loss of parenchyma. The cerebellum may be normal to markedly atrophic. Microscopically, there is encephalitis with macrophages, plasma cells, and lymphocytes infiltrating areas of necrosis and accumulating around vessels. Lesions are sometimes most prominent in the brainstem and spinal cord. The atrophic cerebral cortex may have multifocal areas of necrosis with accumulations of glial cells and perivascular mononuclear cells. In the cerebellum, there may be loss and malpositioning of Purkinje cells and reduced size of molecular and granular layers.

Lesions induced in the *brain* early in gestation, because of extensive destruction of cells, may proceed to hydranencephaly with subsequent arthrogryposis. Lesions produced late in the first trimester usually consist of multifocal encephalitis and proceed only to porencephaly. Infections late in the second trimester may produce lesions consisting of multifocal necrosis and gliosis with less cyst development.

Lesions in the *spinal cord* can be bilateral or unilateral and consist of mineralization of meninges, atrophy of the cord, and hydromyelia. Necrosis and depletion of ventral horn motor neurons may proceed to cavitation. Light or heavy accumulations of perivascular lymphocytes may be present throughout the cord with decreased numbers of axons and hypomyelination in the lateral and central tracts.

Joints of the front legs are more commonly affected than those of the hind, and both may be fixed in either flexion or extension. There is slight-to-marked atrophy of skeletal muscle groups in affected limbs. The muscles are edematous, pale, and flabby to firm. On microscopic examination of muscle, sarcoplasmic nuclei are either swollen or pyknotic. Loss of striations, granular degeneration, and empty sarcolemmic cylinders may be present. Replacement of muscle by connective tissue and fat occurs finally. Well-preserved fibers may be present adjacent to areas of complete loss of muscle mass. Polymyositis, from which the virus can be isolated, has been reported in some infected fetuses.

The **diagnosis** of AKAV infection may be made by demonstrating virus or antibody in affected animals. Virus may be recovered from various fetal tissues and fluids, including brain, spinal cord, cerebral fluid, skeletal muscle, chorioallantois, and amnion. It may be grown on hamster lung cells and can cause reduced litter size, transplacental infection of the fetus, and birth of live, weak young. AKAV can also grow in the brain of intracranially inoculated suckling mice. As the fetus is capable of producing antibody from an early stage of gestation, inferred evidence of the cause of malformation and abortion may be determined by finding specific antibody to AKAV in fetal cavity fluids, including fluids from stored tissues or precolostral blood samples from affected newborn animals.

Aino virus infections of the pregnant uterus in cattle

Aino virus (AINOV, syn. *Shuni virus*) is closely related to *Akabane virus*, and is similarly in the family Bunyaviridae, genus *Orthobunyavirus*, Simbu serogroup. As with AKAV, AINOV is mainly transmitted by the midge *Culicoides brevitarsis* – but has also been isolated from mosquitoes, including *Culex tritaeniorhynchus* and a mixture of *C. pipiens* and *C. pseudovishnui*. The range of the organism, as determined by serum antibody titers, extends along the northern and eastern coasts of Australia (from just within Western Australia to central New South Wales) and is well within the range of *C. brevitarsis*. The virus is also present in Japan. Using antibody titers as evidence of previous infection, fewer species overall and fewer animals within affected species appear to be infected with AINOV compared to AKAV.

Cattle that are infected do not have clinical signs; however, insofar as precolostral antibodies to the organism are found in deformed newborns, *the organism is capable of crossing the bovine placenta and causing abortion*. Lesions consist of placental edema and necrosis, renal tubular necrosis with interstitial lymphoplasmacytic infiltrates, nonsuppurative meningitis, and interstitial pneumonia with mononuclear cells and some neutrophils. Experiments conducted with sheep indicate that, while the virus can infect the fetus after direct inoculation, it does not cross the placenta after inoculation into the pregnant ewe.

Lesions induced in young calves following intracerebral inoculation of AINOV and AKAV are reported to be different. With AINOV, nonsuppurative encephalomyelitis developed first in the cerebrum adjacent to the ventricles and spread to the medulla and the brainstem, but remained mild in the spinal cord. Using animals inoculated with AKAV as controls, nonsuppurative encephalomyelitis was produced in the brainstem and spinal cord only. Intravenous inoculation of virus into susceptible pregnant cows at various stages of gestation may give a more valuable comparison.

Diagnosis is based on immunohistochemistry or fluorescent antibody testing on frozen sections or smears of homogenates of fetal kidney, lung, and liver. Prospective serology on cows at pregnancy diagnosis and at abortion may be useful. Aino and Akabane bunyaviruses can be differentiated by nested polymerase chain reaction.

Cache Valley virus infection of the pregnant uterus in sheep

Cache Valley virus (CVV, syn. *Bunyamwera virus*) is in the family Bunyaviridae, is a serotype of *Bunyamwera virus*, and is widely distributed in North America. Serological data indicate it infects pigs, horses, raccoons, foxes, and domesticated and wild ruminants, including cattle, sheep, caribou, and deer, as well as humans. It is believed to be spread by insects, and has been isolated from a variety of mosquitoes and midges, including *Culiseta inornata, Psorophora columbiae, Aedes sollicitans, Ae. taeniorhynchus, Anopheles grabhamii, An. crucians, An. uadrimaculatus*, and *Culicoides* spp.

There is considerable evidence supporting CVV as the cause of a severe epizootic in a flock of sheep in Texas where, of 360 lambs delivered, 92 were mummified, stillborn, or born with congenital anomalies. Sixty-nine lambs had *arthrogryposis and hydranencephaly*. All of the ewes bearing affected lambs had neutralizing antibody to CVV and affected lambs had precolostral antibody to the virus. In the months before pregnancy, 5% of ewes had antibody to the virus and after pregnancy, 63.4% were positive. Following the outbreak, a sentinel sheep was placed in the area and CVV was eventually recovered from a blood sample.

Examination of 15 lambs stillborn at term during the epizootic revealed that central nervous system, and muscle and joint lesions were frequently present in the same animal, and lesions between lambs mainly differed in severity. Gross lesions in limb joints consisted of articular rigidity with articulations held in the flexed position. The limbs appeared long for the size of the body. In addition, kyphosis, scoliosis, and torticollis were frequently observed. Muscles associated with the affected limbs and spine were described as shrunken, pale, and firm. Lesions in the brain consisted of *hydrocephalus, porencephaly, and hydranencephaly*. The cerebrum, cerebellum, and spinal cord were often markedly reduced in size and the cerebellum was occasionally mildly lissencephalic.

Microscopic lesions were observed in skeletal muscles, brain, and two placentas. In affected muscle, fibers were small, lacked striations, and nuclei were sparse. Fibers were separated by loose connective tissue and adipocytes; rarely, a few neutrophils and mononuclear cells were present. Histologic examination of the brain confirmed gross findings, and cavities not visible grossly were occasionally observed. In regions of marked hydranencephaly, the cerebral cortex was reduced to a few layers of neurons within the meninges. Entire lobes of the cerebellum were often absent but adjacent lobes were often near-normal, with only minor loss of cells in the molecular layer. The density of axons in the spinal cord was markedly reduced, especially in dorsal tracts, and, whereas ventral horn neurons were only slightly reduced in the cranial cord, hardly any remained in caudal portions. Inflammatory cells were scant in lesions, except in two of the five placentas examined wherein a mild perivascular neutrophil infiltrate was evident.

Inoculation of 36 ovine fetuses in utero with CVV has added further credibility to the association of CVV as the cause of the epizootic. Following in utero inoculation of the virus, several of the fetuses developed arthrogryposis and hydranencephaly; some were mummified, others died and were absorbed, and a few had oligohydramnios. Lambs infected at 27–35 days of gestation had the greatest mortality rate, while lambs infected between days 36 and 45 of gestation had more congenital anomalies. Virus was recovered from fetuses before 69 days but not after 76, regardless of when they were infected, and this was coincident with the development of neutralizing antibody in the fetus. The virus was recovered from allantoic fluid in 11 of 17 fetuses euthanized at less than 76 days' gestation.

The **diagnosis** of CVV infections resulting in fetal loss and congenital anomalies in lambs is most easily accomplished by examining precolostral serum or cavity fluids of lambs with arthrogryposis and hydranencephaly for antibodies to CVV. Attempts to demonstrate virus in tissues of lambs born with congenital abnormalities may be futile, as by the time of birth the virus is rarely present. Differential diagnoses should include infection by *Akabane virus*, as the lesions are remarkably similar.

Rift Valley fever virus infections of the pregnant uterus in cattle and sheep

Rift Valley fever virus (RVFV) infects many domestic, wild, and laboratory animals and humans. It occurs in at least 18 countries over a 6700-km north–south range in Africa, plus Saudi Arabia. *Infection by RVFV causes a disease characterized by rapid onset and high mortality in lambs, low mortality in adult sheep and calves, and even lower or no mortality in cattle. There is frequently a high rate of abortion, approaching 100% in sheep and cattle.* People may also become infected and develop influenza-like illness; mortality is generally low, but morbidity is high and the degree of debility often extreme. *Hepatic necrosis is the prominent lesion, and occurs in all affected species and age groups, including the fetus.* Host resistance to fatal hepatic disease has been shown in laboratory animals to be inherited as a simple Mendelian dominant gene. Susceptibility is age- and sex-related; the young are more susceptible, and males less resistant than castrates and females. Although two-thirds of sheep are genetically resistant to fulminant hepatic disease, *sheep are regarded as the most susceptible domestic animal.*

The virus is in the family Bunyaviridae, and is the type species of genus *Phlebovirus* (Zinga virus is a strain of RVFV.) *It is transmitted primarily by mosquitoes*, and *Culex pipiens* is a major vector in parts of Africa. Generalized infection in the mosquito is necessary before transmission occurs effectively, and movement of virus from the insect gut is facilitated by the presence of microfilariae in ingested blood. *Aedes* spp. are capable of transovarial transmission. *Aedes albopictus*, a strain of mosquito in the USA, can transmit the virus and movement of animals either incubating infection or in viremia raises the possibility of international spread of the virus. Biting midges and ticks are also implicated in transmission. The virus probably does not spread from animal to animal in the absence of insects; however, experimentally the virus can be transmitted by just about every route, including aerosols or application into nasal passages, to scarified skin or on the conjunctiva. *Aborted fetuses and membranes have a very high titer of virus.* Epizootics often follow a period of heavy rain, particularly after drought, and outbreaks may be separated by periods of 10–15 years without a case.

In mature sheep or cattle, the disease is manifest in *peracute, acute, subacute, chronic, and convalescent forms.* In sheep, the subacute form, in which the animal is febrile for 24–96 hours, is common, and up to 100% of pregnant ewes can abort during this phase or when convalescing. In cattle, the peracute form is rare and abortions occur during the acute or convalescent period and vary from 10 to 85% of pregnancies. Deaths in cows are uncommon. Infertility occurs in both sheep and cattle and may follow retention of fetal membranes and endometritis. Signs are unpredictable in goats. They tend to be less susceptible than sheep, but if infected can abort.

During viremia, the organism is carried to the placenta and fetus, where *the liver appears to be the primary site of multiplication.* Hepatocyte destruction is probably related to the repeated cycles of virus growth and release of virus from infected cells.

Lesions are much the same in cattle or sheep fetuses and, except for one report where experimental inoculation of pregnant ewes with an attenuated RVFV resulted in hydranencephaly and arthrogryposis, *infection by RVFV usually results in death of the fetus* in utero. This occurs at any gestational age and, as it occurs rapidly, the fetus is aborted in an autolysed state. On gross examination, the liver is swollen and discolored orange to brown and occasionally to dark red. Microscopically, the most consistent lesion seen in almost 100% of fetuses examined is *multifocal to massive hepatic necrosis.* A few degenerating neutrophils may be present in these lesions. *Acidophilic intranuclear inclusions* of various shapes (fusiform, round, oval) are frequently present in hepatic cells of ovine fetuses and are helpful in the diagnosis. These are seen less often in bovine fetuses and may be difficult to find when autolysis is advanced. Mineralization of individual or clusters of hepatocytes is also common. Cholestasis may be evident in canaliculi. Other lesions reported include degeneration of lymphocytes in spleen and lymph nodes, and degenerative lesions in heart muscle and renal tubules.

The hepatic lesion is considered diagnostic; however, in areas where the condition is not endemic, definitive **diagnosis** depends on identification of the virus. It can be detected early in infection in blood or serum by reverse transcriptase-polymerase chain reaction. It is abundant in fetal tissues and placenta and may be cultured or detected using the indirect fluorescent antibody technique on frozen sections of liver, or by immunohistochemistry. Differential diagnoses in sheep include infections by *bluetongue virus* and *Wesselsbron virus.*

Circovirus postweaning multisystemic wasting syndrome

Porcine circovirus type 2 (PCV2), family Circoviridae, genus *Circovirus*, is associated with the postweaning multisystemic wasting syndrome (PMWS), and appears to act with other cofactors that cause stimulation of the pig's immune system. Antibody to the agent has been demonstrated for several years and it is suspected that a new highly virulent PCV2 virus has recently emerged in several countries. Clinical PMWS has not been reported in Sweden; however, antibodies to PCV2 are present in many Swedish pigs tested. PMWS was first reported in western Canada in 1991 and has now been found in the USA and in many European and Asian countries. *The disease primarily affects pigs 5–18 weeks of age and is characterized by failure to grow and eventual emaciation.* Affected pigs may have stomach ulcers in addition to a wide variety of lesions, including pneumonia and diarrhea.

A *reproductive failure syndrome* has been observed in several herds and is characterized by late-term abortions of mummified, macerated, or autolysed piglets, and piglets born weak or stillborn. Lesions in these piglets included enlargement of the liver, congestive heart failure, with excess fluid in the thorax and abdominal cavities. The heart may be enlarged and irregular in shape and on histological examination extensive areas of myocardial degeneration, edema, and necrosis with mild fibrosis and diffuse moderate infiltrations of lymphocytes and macrophages may be observed. The virus can be demonstrated by immunohistochemistry in heart muscle cells. No other viruses were detected in this investigation. Stress factors and co-infections with other porcine viruses were not detected; however, environmental, husbandry, and genetic factors may be important in the progression of clinical PMWS.

MISCELLANEOUS LESIONS OF THE POSTPARTUM UTERUS

Endometrial cysts, *adjacent to caruncles, develop in some cows and ewes during the process of uterine involution* (Fig. 4.138). Adhesion of the caruncular stalk to adjacent glandular tissue causes blockage of the underlying glands. The retention cysts enlarge progressively with age, and care must be taken to differentiate them from estrogen-linked cystic hyperplasia.

Subinvolution of placental sites in the bitch is manifested clinically by a prolonged, blood-tinged vaginal discharge. In the normal bitch, overt uterine bleeding usually ceases within 7–10 days following whelping, but the affected bitch may bleed for several weeks or months. In some cases, the blood loss causes severe anemia and occasionally death. *Ellipsoidal enlargements*, located in the areas of previous placental attachment, are evident in the uterine cornua (Fig. 4.139). The endometrium in the affected areas is hemorrhagic, irregularly thickened, and gray to brown. The endometrium between the enlargements is normal in appearance. The surface epithelium is often detached, but when present, it has heavily vacuolated cytoplasm, indicating progestational stimulation. Corpora lutea are invariably present, but progesterone levels have been low in the few cases in which the determination was made. The uterine mass adjacent to the uterine lumen is composed of an admixture of amorphous eosinophilic debris, thrombotic material, degenerating placental site tissue, and regenerating endometrium (Fig. 4.140). The deeper tissue is permeated with numerous irregular-shaped cells with large nuclei

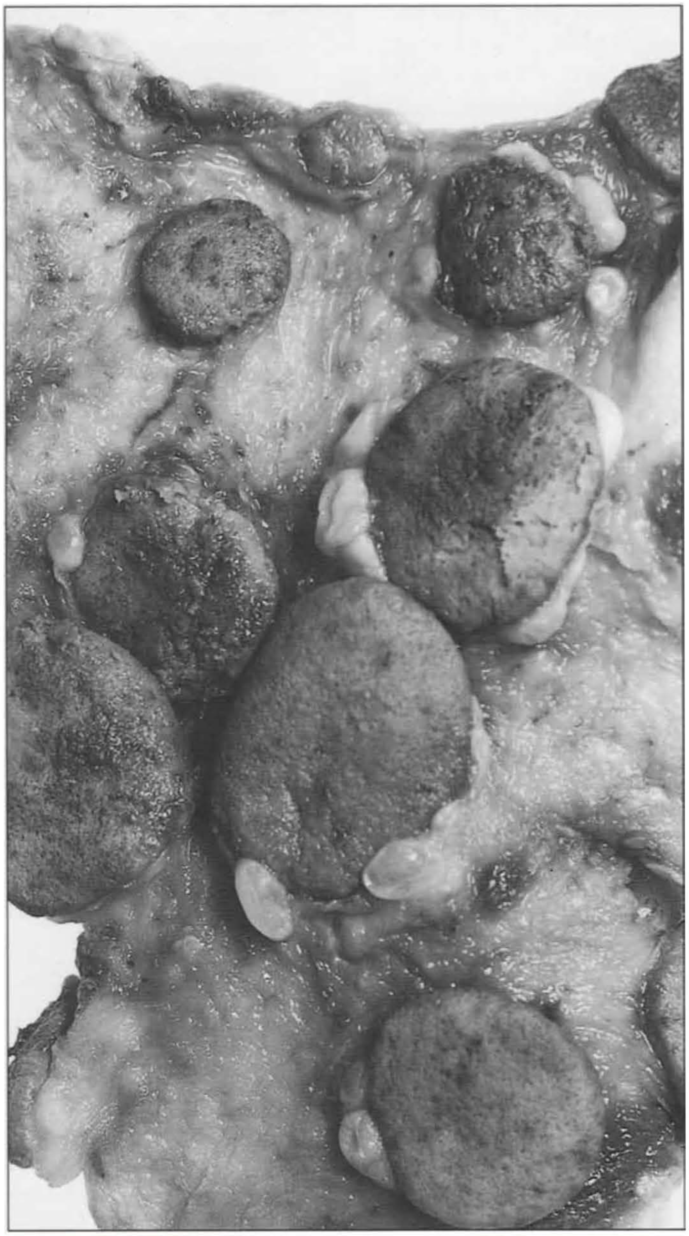

Figure 4.138 Endometrial cysts in a cow.

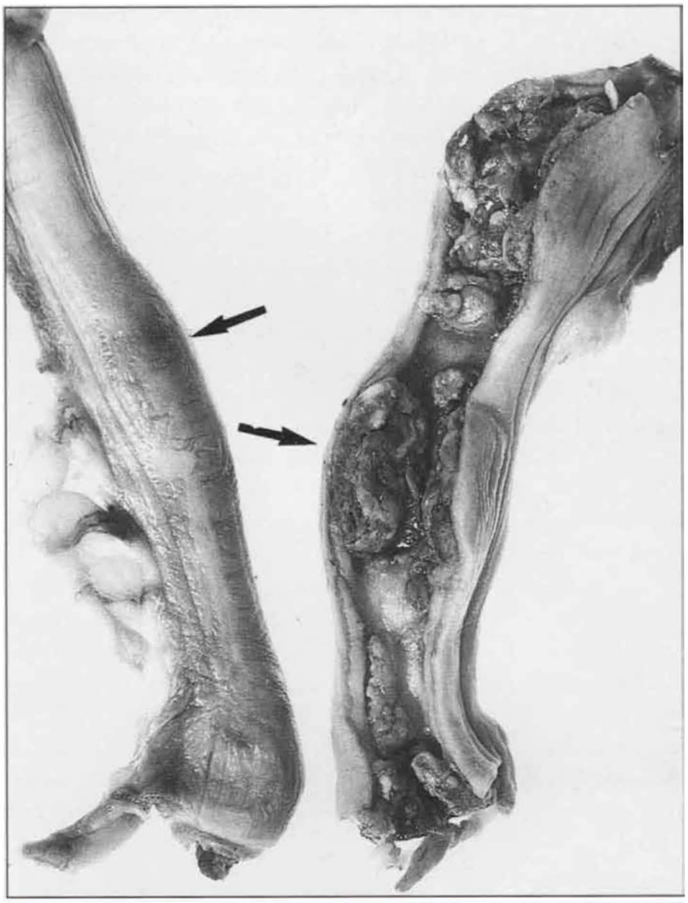

Figure 4.139 Subinvolution of placental sites in a bitch. Note fusiform enlargement of uterine horns at sites of failure of involution (arrows).

and abundant vacuolated cytoplasm (Fig. 4.141). They are interpreted as syncytial trophoblasts or alternatively as decidual cells, and are far more numerous than in the normal gravid uterus. Some degree of invasion of the myometrium by these cells is not unusual, and in some cases there is perforation of the serosa, allowing uterine contents to escape into the peritoneal cavity. The condition appears to be more prevalent in young bitches, but *the cause has not been established.*

Pathology of the cervix, vagina, and vulva

PATHOLOGY OF THE CERVIX

Cysts of the cervix occur in cows, and probably all are *retention cysts* formed by fusion of the rugae. Loss of the original epithelium of the rugae is first necessary and may be incidental to the lacerations of parturition, artificial insemination, or inflammation. The cysts are usually small and not significant. Larger ones may cause partial occlusion of the cervical canal, but this is seldom of importance.

Stenosis of the cervix is extraordinary. It is *acquired* rather than congenital, and consists of fusion across epithelial surfaces and scarification. It may follow severe laceration or long-standing inflammation.

Cervicitis is not in itself an entity but, instead, is an *extension of endometritis or vaginitis*. The mucus-secreting epithelium provides good defense against bacterial invasion and, if the epithelium breaks down, it exposes densely arranged connective and muscular tissues, which are not especially sensitive to the actions of bacteria. In the cow, the epithelium lining the external os and the adjacent few rugae is of the simple vaginal type, and this is more susceptible to irritation than the mucus-secreting surface cranial to it. Most inflammations then are superficial, but there are some exceptions, such as necrobacillosis. The circumstances in which cervicitis occurs have been mentioned in the section on pathology of the uterus or will be mentioned

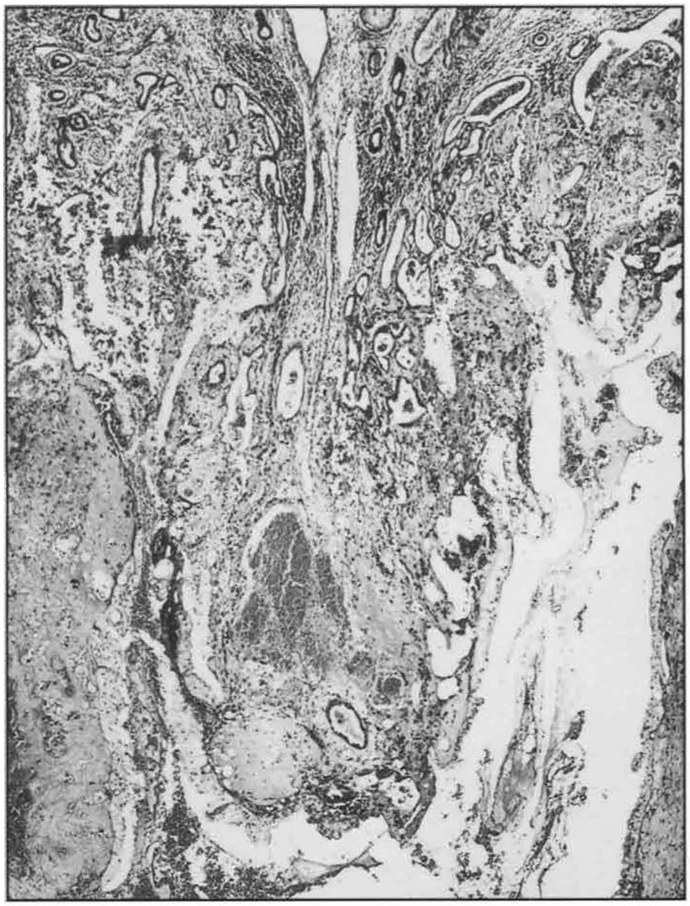

Figure 4.140 Subinvolution of placental sites in a bitch. Note hemorrhage and necrotic debris in pedunculated endometrium.

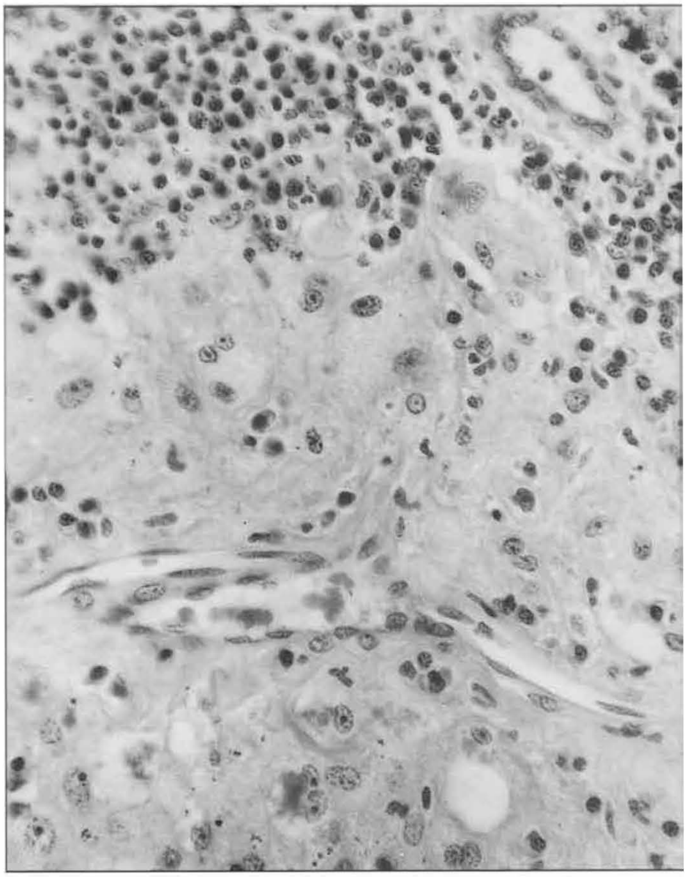

Figure 4.141 Decidual cells and surrounding inflammatory cells deep in the placental site, in subinvolution of placental sites.

under pathology of the vagina and vulva, below. The usual form of bovine *simple cervicitis* is seen as a swelling of the caudal annular rugae, which are edematous and hyperemic. They soon protrude through the external os into the vagina, and thin mucopurulent exudate accumulates between the folds and collects in the vagina. Histologically, there is epithelial degeneration and desquamation and infiltration by inflammatory cells that are predominantly mononuclear. Neutrophils penetrate the epithelium and become mixed with mucus, or in more acute cases there may be frank suppuration. Cervicitis is not usually more severe than this, although in older cows the prolapse and tumefaction of the rings may be grossly obvious. Although degrees of prolapse result from inflammation, they may also predispose to it. Slight but progressive degrees of eversion of the cervical rings occur with succeeding pregnancies to expose portions of the cervical mucosa to the contaminated environment of the vagina. *Chronic cervicitis* may lead in time to enlargement and induration of the cervix with some stenosis, but enlargement is not a criterion of inflammatory sclerosis. Discrete *cervical abscesses* or *suppurative fistulous tracts* occasionally result from accidental injury acquired during uterine irrigation or artificial insemination.

PATHOLOGY OF THE VAGINA AND VULVA

Cysts in the vagina or vulva are not important in themselves, but they do have some diagnostic significance. They occur as *cystic dilations in Gartner's ducts and Bartholin's glands* in cattle. Gartner's ducts are remnants of the embryonic mesonephric (Wolffian) ducts, which lie, one on each side of the floor of the vagina, beneath the epithelium. They are invariably present to some degree in cattle, although, when normal, they are only detectable microscopically as discontinuous ducts lined by simple epithelium and found in the cranial vagina and disappearing caudally. They become cystic in cows poisoned with highly chlorinated naphthalenes, in cows with ovarian follicular cysts, and occasionally following acute vaginitis. With lesser degrees of dilation, the cysts are more readily palpable than visible, but in well-developed instances they are clearly visible through the elevated and thinned vaginal wall (Fig. 4.142). The cysts may be isolated or they may have a string-of-beads disposition, or the whole duct may be present, dilated to 1–2 cm and tortuous. *Cysts of Bartholin's glands* occur under the same stimuli, but chiefly as a consequence of inflammation. The glands lie one on each side of the floor of the vestibule and normally are about 3 × 1.5 cm in dimension. They become visible when enlarged, especially if the vestibular mucosa is slightly everted. These glands are very sensitive to estrogens, responding with the elaboration of thin mucus and hyperplasia of the ductal epithelium. Gross exaggeration of responses in hyperestrogenism accounts for the cystic development. Large retention cysts follow inflammatory stricture of the short excretory ducts. Abscessation may follow localization of infection in the cysts.

Ruptures of the vagina and vulva are quite frequently acquired as *parturient injuries*. The mucosa alone may be ruptured, or the

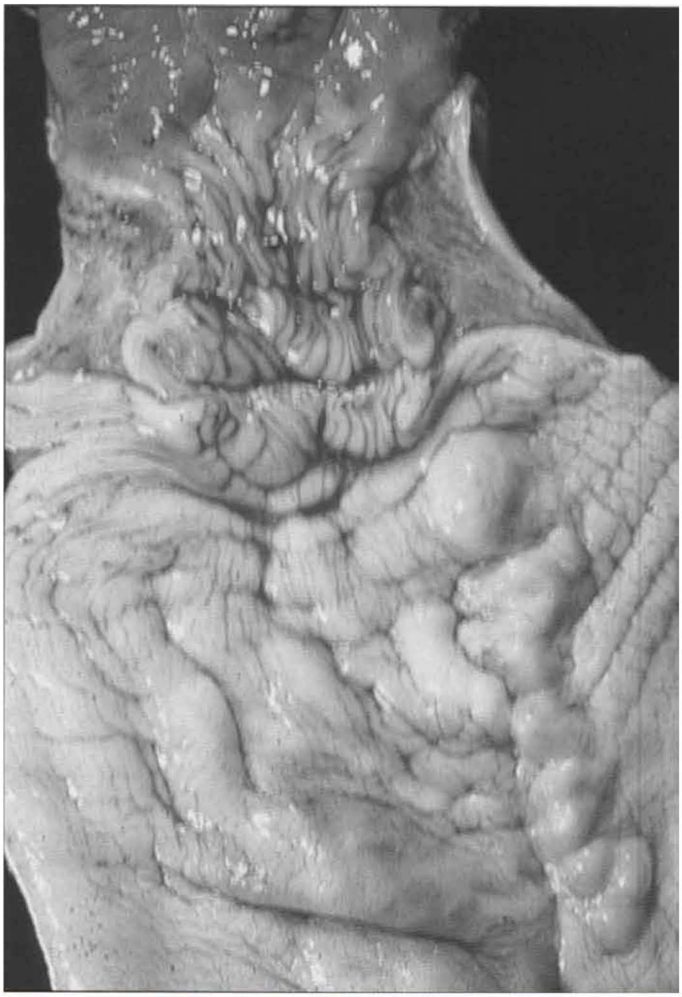

Figure 4.142 Cystic segment of a mesonephric duct in the vagina of a cow (cystic Gartner's duct). These cysts are common in cattle and are found in the ventrolateral area of the floor of the cranial vagina.

entire thickness of the vaginal wall. Hemorrhages occur into the vagina or the perivaginal wall from fetal pressure or vascular disruption. *Pelvic fat may herniate into the vagina*; it is often mistaken for a neoplasm. Defects that extend deeper than the mucosa heal with cicatrization, which may, in turn, result in partial stricture. Otherwise, the outcome depends on whether the lacerations become infected and, if so, with what. Occasionally, diffuse phlegmon, abscess, gangrene or peritonitis are sequelae.

Tumefaction of the vulva

Tumefaction of the vulva is a physiological response to estrogens. Vulvar enlargement may be marked during the normal estrous period or may be persistent when resulting from exposure to endogenous or exogenous estrogens. Abnormal patterns and concentrations of endogenous estrogens may occur from *cystic follicular disease, estrogen-secreting tumors (granulosa cell tumors), or from exogenous sources such as mycotoxins.* Vulvar tumefaction is most common in the sow and bitch, and must be differentiated from vulvitis (bite wounds), physical trauma, or dystocia.

Vulval tumefaction in **swine** may be due to exposure to mycotoxins. A distinctive syndrome characterized by vulval hyperemia and edema occurs in swine associated with the feeding of moldy grains. The mycotoxin that causes this estrogenic effect is *zearalenone or F-2*, which is produced by at least four different *Fusarium* species, *F. graminearum* being the most common.

Young gilts are chiefly affected, older animals being more resistant. There is remarkable edematous swelling of the vulva and vagina, which may be severe enough to lead to eversion and prolapse of the mucosa. Prolapse of the vagina may occur in up to 30% of cases, and secondary rectal prolapse occurs in a lesser percentage. The uteri of affected animals may be enlarged by endometrial gland hyperplasia and edema. The ovaries become inactive and atrophic. Gilts may also show mammary gland enlargement with squamous metaplasia of the ductal epithelium. Decreased libido, testicular atrophy, and balanoposthitis have been reported in young boars.

Strains of *Fusarium* vary in toxigenic potency, in regard not only to zearalenone but also to trichothecene toxins, which, if produced in quantity, may broaden the clinical picture to include anorexia and vomition.

Inflammatory diseases of the vagina and vulva

The mucous membrane of the vagina and vulva shares, with mucous membranes in general, a sensitivity to irritants. Although the vagina is of paramesonephric duct origin, the original epithelium is replaced by stratified squamous epithelium from the urogenital sinus. This epithelium proliferates and matures under the influence of estrogen and is then more resistant to infection. This enhanced resistance may be due to mechanical factors in the thickened keratinized epithelium and to local production of lactic acid from the glycogen that is deposited in the epithelium under the influence of estrogens.

Granular venereal disease

Papular eruptions of the vulval mucosa are common in most domestic species but are best known in the *bovine* species by the above name or as "*nodular venereal disease*" or "*granular vaginitis.*" The term vaginitis is a misnomer, as the papules are strictly limited to the vulval mucosa and are not found in the vagina, although in acute cases there may be an associated nonspecific vaginitis. Vulval granules may be found in any herd, affecting animals of any age, but are usually more prominent in heifers bred naturally. They are much less common in pregnancy and are almost never present about the time of parturition. In severe cases, the papules may be found on all aspects of the vulval mucosa, but they are usually clustered in the ventral commissure about the clitoris as pale or pink elevations a few millimeters in diameter and covered by a normal intact vulval mucosa. When numerous, they are likely also to be more active, larger, often coalescent, congested, and red, with concurrent catarrhal vulvitis and vulval swelling. The overlying epithelium is then easily injured and bleeding occurs freely from the papules. The resting papules are composed of respectably organized lymphoid follicles (Fig. 4.143).

When the vulval mucosa is irritated, these become congested, with small intrafollicular hemorrhages and edema, and hyperplastic, the mitotic frequency being quite high. The same lesions occur on the penis and prepuce of the bull and often persist for many months, as do those of the vulva. These papules have been produced experimentally with ureaplasmas and occur commonly in herds with natural *Ureaplasma* infections but are *not specific for this organism.* The development of subepithelial lymphocytic foci is a characteristic response of mucous membranes to mild persistent or recurrent

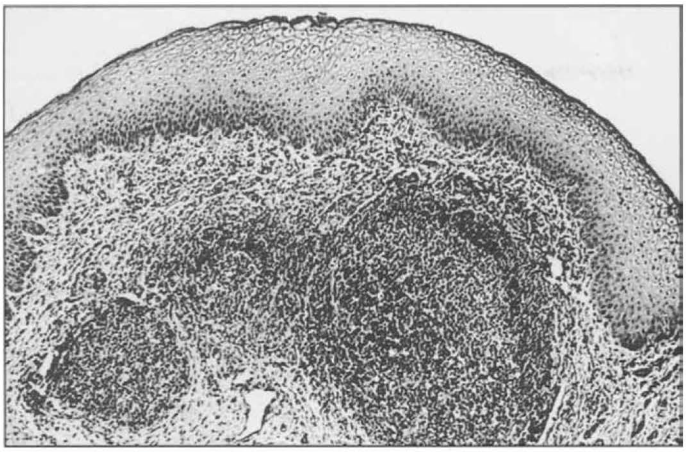

Figure 4.143 Bovine granular venereal disease, with submucosal lymphoid hyperplasia.

irritation and the simplest explanation of granular venereal disease is that *it is the result of mild inflammation of the vulval mucosa.*

Infectious bovine cervicovaginitis and epididymitis ("epivag")

This is a specific infectious disease that has been an important cause of infertility in east and southern Africa. A slow-growing *cytomegalovirus of the Bovine herpesvirus 4 group* has been recovered from infected animals. In limited studies, these isolates have not reproduced the full spectrum of clinical signs, so there remains some uncertainty about their role in the disease. The slow-growing herpesviral strains are not serologically related to the *Bovine herpesvirus 1* of infectious bovine rhinotracheitis.

Natural transmission is solely by coitus. Experimental transmission is easy if infective discharges are placed in the vagina or prepuce. After incubating for a few days, diffuse purple inflammatory streaks or patches develop in the cranial vagina, to be followed by the development of copious tenacious creamy discharge in which there are large numbers of neutrophils but few or no organisms. The infection spreads readily from the vagina to the cervix and uterus, also with the production there of the same copious pus. About 25% of infected females are sterile because of the development of *chronic salpingitis with hydrosalpinx and bursal adhesions.* In the bull, there is early but slight palpable enlargement of the spermatic cord and epididymis. The disease usually commences in one epididymis but later involves both organs and spreads from the tail of the epididymis to the head of it and ultimately to the testicle. The lesion is apparently an *interstitial epididymitis* with the production of excessive peritubular fibrosis and tubular obstruction. Testicular changes are probably secondary to those in the epididymis and to obliterative adhesions in the cavity of the tunica vaginalis. Similar productive inflammatory lesions occur in the ampullae and the seminal vesicles.

Infectious pustular vulvovaginitis of cattle

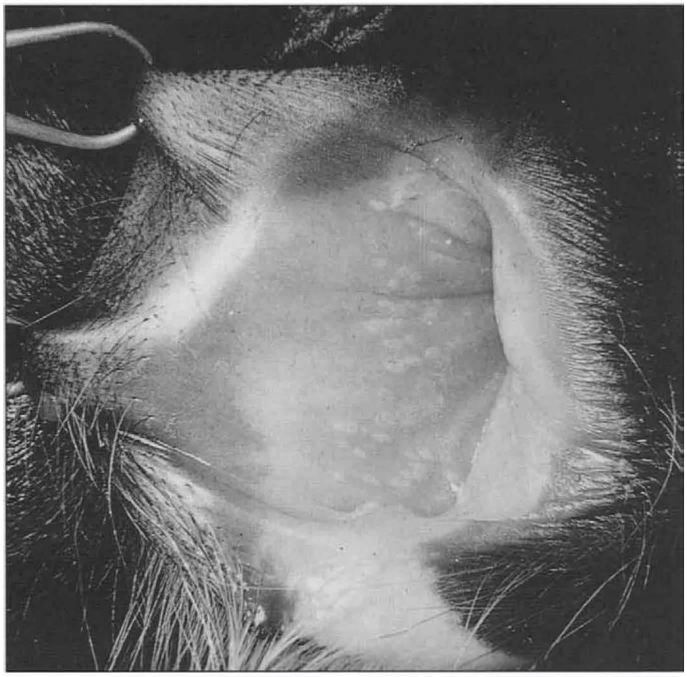

Figure 4.144 Multifocal necrotizing vulvitis caused by *Bovine herpesvirus 1.* (Courtesy of Baker JA et al. and Cornell Vet 1960;50:156–170.)

We are assuming for this description of infectious pustular vulvovaginitis that it is the disease that for many decades has been variously termed vesicular venereal disease, vesicular vaginitis, coital exanthema, coital vesicular exanthema, and Blaschenausschlag. The assumption is probably valid, but proof is lacking and may no longer be obtainable. Infectious pustular vulvovaginitis is caused by the same herpesvirus (*Bovine herpesvirus 1*) that causes infectious bovine rhinotracheitis (see Vol. 2, Respiratory system), or at least is caused by a subtype of that virus that is serologically indistinguishable from it. As a rule, nasal and vaginal infections behave epidemiologically as distinct diseases, although occasionally the syndromes occur together in individual animals. The infection can be transmitted to sheep and goats, producing vaginitis.

Infectious pustular vulvovaginitis is *highly contagious.* It is frequently transmitted by coitus, but it can also be transmitted by other mechanical means and is contagious by close contact. It may involve individual or a few animals in a herd, but frequently spreads rapidly to involve all exposed females in a few days. The disease subsides in about 10 days, leaving immunity that is fragile and transient. Reinfection can occur, but early reinfection produces only mild disease.

The incubation period is 1–3 days but may be as brief as 12 hours. The lesions are restricted to the genital tract, but a viremic phase probably occurs because there is early fever and leukopenia. Initially, the vaginal and vulval mucosa is hyperemic with focal hemorrhages in the lymphocytic follicles of the submucosa. *The severity of the vulvovaginitis increases rapidly, and edema of the vulva and mucopurulent vaginal discharge develop.* The focal lesions replace the hemorrhages over the lymphoid follicles and consist of small (2–3 mm) pock-like foci, slightly elevated, pale, soft, and friable (Fig. 4.144).

The focal lesions, being related to the lymphoid follicles, may be in short linear arrangements. The epithelium in the focal lesions erodes or ulcerates so that in a few days the foci are flat, gray, semitransparent plaques the size of the original lesions.

The virus is epitheliotropic, the initial and most severe alterations occurring in the epithelium of the vagina and vulva. There is ballooning degeneration of the epithelial cells, and, at about 24 hours, *intranuclear inclusions* can be found in the epithelium (Fig. 4.145A).

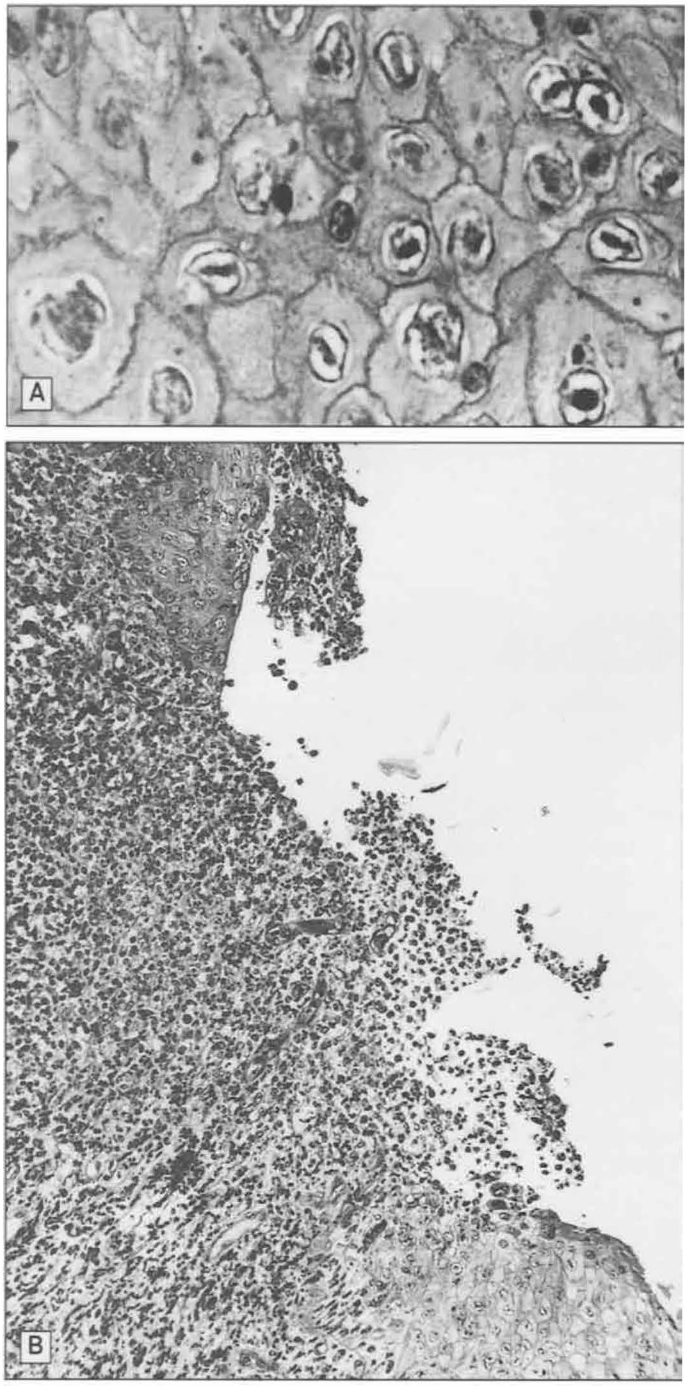

Figure 4.145 A. Intranuclear inclusion bodies in vaginal epithelial cells in *Bovine herpesvirus 1* infection. **B.** Histologic detail of **(A)**. Ballooning degeneration and ulceration of epithelium.

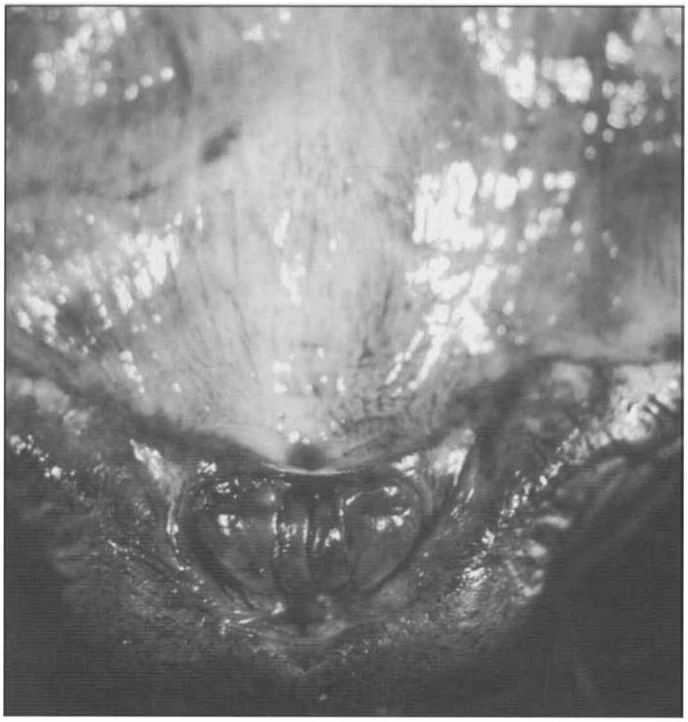

Figure 4.146 Contagious equine metritis. The clitoris and clitoral fossa of a mare infected with *Taylorella equigenitalis* appear grossly normal but are the sites of chronic infection in the mare. Mats of bacteria can be found on the mucosal surface of the sinuses and crypts of the clitoris.

The inclusions are lightly acidophilic or amphophilic and large; they can be found for 3–4 days, by which time the lesion has reached its zenith and is beginning to resolve. The infected cells undergo necrosis, and epithelial disruption and ulceration occur, accompanied by an intense infiltration by neutrophils (Fig. 4.145B). Vesicles and true pustules do not form. Acute inflammation occurs in the lamina propria, with hyperemia and edema and the exudation of numerous plasma cells and lymphocytes. Many of the small vessels are occluded by adventitial and endothelial swelling. The lymphocytic follicles are remarkably hyperplastic and edematous, and their outlines are obscured by the infiltrating cells in the lamina propria. Resolution occurs in about 8 days, with hyperplastic lymphoid follicles and slight epithelial thickening as residues.

Although most cows that are served naturally by infected bulls do not appear to experience infertility, susceptible heifers, which are inseminated with semen containing virus, fail to conceive. Intranuclear inclusions may be found in the epithelial cells of the zona compacta within 48 hours but are absent by 72 hours after exposure. The surface epithelium and the underlying connective tissue become necrotic and infiltrated with neutrophils. There is pronounced edema of the lamina propria and infiltration of mononuclear cells, especially lymphocytes. The oviducts are involved, but to a less severe degree.

The virus can produce similar lesions on the mucous membrane of the penis of infected bulls. Since recrudescence with viral shedding is a feature of this, as well as other, herpetic diseases, animals with inapparent infections can also transmit the disease.

A herpesvirus identified as *Equid herpesvirus 3* produces a comparable genital disease in horses, *equine coital exanthema.* It is discussed with diseases of the penis, in Vol. 3, Male genital system.

Contagious equine metritis

Contagious equine metritis, caused by *Taylorella equigenitalis,* is a sexually transmitted disease of horses. As discussed in the section of this chapter on endometritis, above, acute infection of mares causes purulent endometritis and cervicitis. In mares that have become carriers the *Taylorella* organisms reside within the crypts and fossa of the around the clitoris. Although the mare's clitoral area, shown

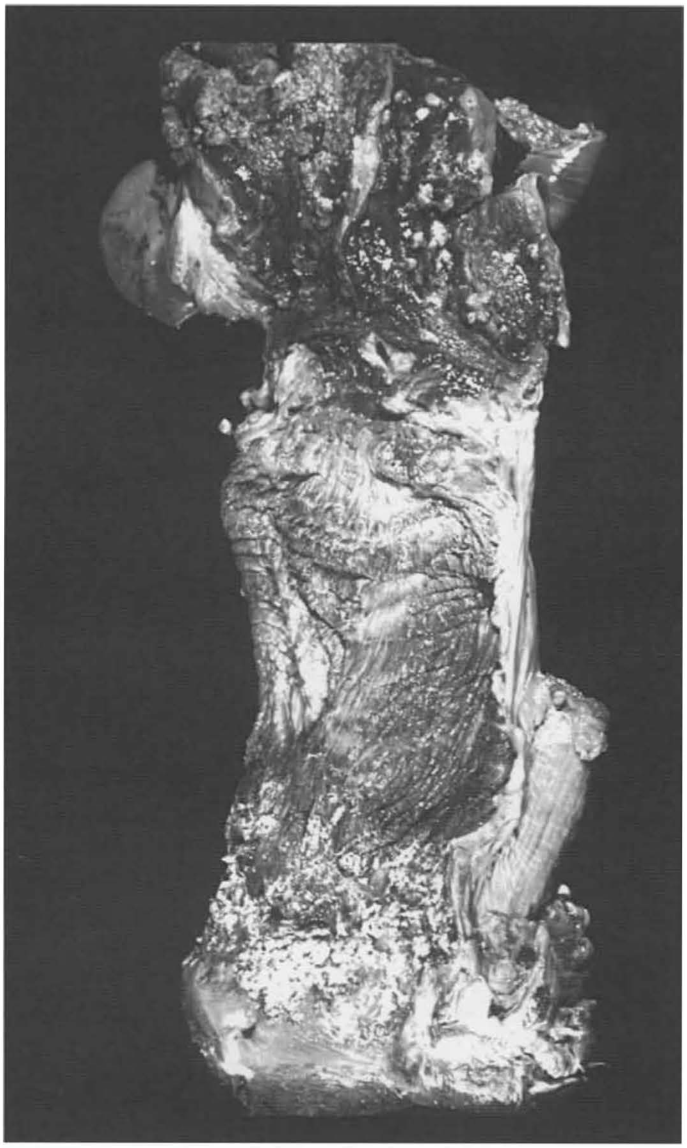

Figure 4.147 Necrotizing vaginitis in a cow, associated with dystocia and associated pressure necrosis.

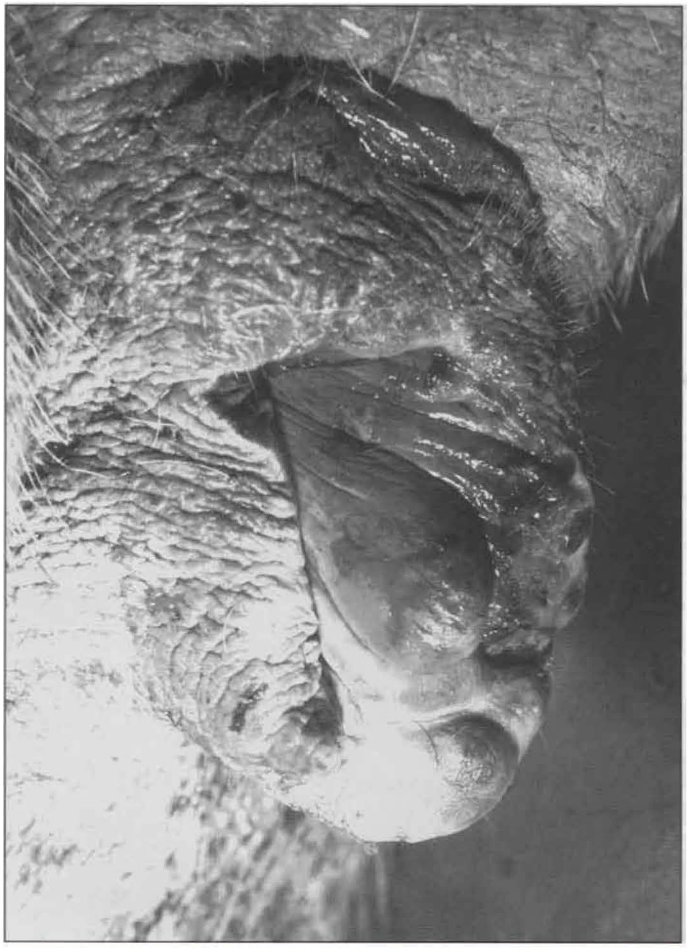

Figure 4.148 Disfigured vulva of a sow, resulting from trauma during delivery.

in Figure 4.146, is grossly normal, she had large numbers of *Taylorella* coccobacilli within the clitoral fossa that was associated with only a mild lymphocytic reaction. An atypical *Taylorella* sp. also capable of causing transient endometritis and endometritis has been isolated from *donkeys* in the USA.

Necrotic vaginitis and vulvitis

Necrotic vaginitis is a deep diphtheritic inflammation of the vaginal mucosa; it occurs in two fairly distinct syndromes, either vulvovaginitis or cervicovaginitis. *Necrotic vulvovaginitis* is uncommon, but may involve a number of cows in a herd. It is primarily due to trauma with contamination, often the result of bite wounds by pigs or dogs. *Necrotic cervicovaginitis* (Fig. 4.147) is a complication of parturition and is chiefly observed in ewes and cows as a consequence of dystocia. A number of influences, mainly prolonged pressure necrosis, laceration, and abrasion, usually acting in combination, is responsible for the lesion. Severe necrotic cervicovaginitis is frequently fatal, either in association with direct extension of the inflammation to the peritoneum or in association with the uterine complications of prolonged dystocia and fetal emphysema.

Lacerations associated with dystocia commonly occur in mares, sometimes extending to involve the rectum and perineum. *Scarring* of the vulva from previous trauma associated with delivery is a common finding in large domestic animals (Fig. 4.148). *Primary skin tumors* that occur in the perineal area and frequently involve the vulva include squamous cell carcinomas and melanomas in mares (Fig. 4.149).

Dourine

Dourine of horses and their relatives is caused by ***Trypanosoma equiperdum*** and is *primarily a venereal disease*. The other trypanosomiases of domestic animals are discussed in Vol. 3, Hematopoietic system, being essentially hemic infections with arthropod vectors. Dourine differs from other trypanosomiases in that the organisms are in the blood only intermittently or in very virulent infections, and transmission is effected not by blood-sucking insects but by contact of infected mucous membranes. *Natural transmission is by coitus*, so the disease is almost exclusively one of stallions and breeding mares. Rare cases occur in unbred animals and in young foals. The disease prevails

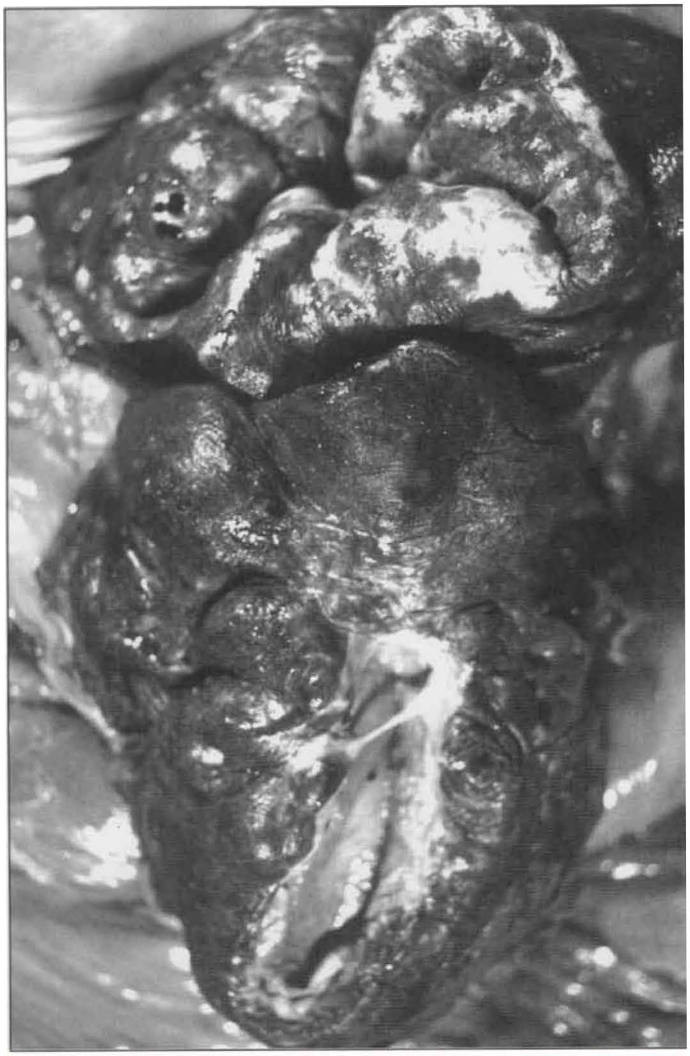

Figure 4.149 Multifocal nodular pigmented masses involving the vulva and perineum of a mare. This **malignant melanoma** had also metastasized to regional lymph nodes. These are common neoplasms that involve the vulva and perineum of the mare. Squamous cell carcinomas also occur in this area.

in the Balkans, much of Africa, Asia, and South America. It has been eradicated from most of Europe and North America.

Strains of *T. equiperdum* vary considerably in their virulence, although not notably in their capacity to infect. Irrespective of the route of experimental infection in horses, the trypanosomes demonstrate some predilection for genital mucosae. Following natural infection, the organisms are frequently numerous in vaginal discharges and the male urethra. There are periods, however, sometimes of several weeks or months, in which the organisms are not present in these sites, so infected animals are not always infective for others at breeding. The organisms penetrate intact mucosa at the site of implantation and proliferate in the submucosal lymph spaces. The incubation period may be several weeks or months during which time trypanosomes are present in the genital discharges, so there is a possibility that they may proliferate in the lumen of the genital tract for long periods before invading the tissues. From the initial lesions, the organisms are disseminated in the blood to other parts of the body, and edematous swellings occur where they localize. Infection of the blood may be intermittent or continuous, and there may be few organisms or many, depending on the virulence of the strain and the susceptibility of the host. Strains of low virulence may not be demonstrated in the blood by direct smears, but may be demonstrated by centrifuging plasma or directly by transfusing blood in large volumes. In these mild infections, it may also be possible to demonstrate the organisms in genital washes or discharges, but diagnostic problems are simplified by an efficient complement-fixation test.

The signs and course of the infections vary considerably depending on the virulence of the organism and on the susceptibility of the host. The resistance of the host can be greatly modified by climatic conditions, physical condition, intercurrent disease, nutritional status, and so forth, and the South African varieties of the disease can be asymptomatic in animals that are well husbanded. Animals affected with this insidious type of the disease do act as carriers and reservoirs of infection. When the infection is attended by clinical signs, the course is variable; it may be severe and fatal in a few weeks, fatal after a chronic or intermittent course of from several months to 2 years, or clinical recovery may occur.

The signs of dourine can be divided into genital, cutaneous, nervous, and general manifestations, which occur separately or concurrently. The initial signs are usually genital, but may be nervous or cutaneous. The incubation period of the genital signs varies from several days to several months, during which the organisms are present in genital discharges or washings. The external genitalia are swollen and doughy, but characteristically the swellings are neither hot nor painful. The degree of swelling varies considerably from case to case and periodically in an established case, with a tendency to be permanent due to induration in chronic infections. The swelling, when severe, extends to the perineum and ventral abdominal wall. The lymphocytic follicles of the mucosa of the female genitalia become hyperplastic and ulcerate, and at this stage there may be copious fluid discharge. In males, the swelling involves the glans penis as well as the prepuce, and may cause prolapse of the urethra and penis. In virulent infections, flat circular ulcers develop in the glans penis. *Healed ulcers in both males and females often remain as depigmented scars*, and pigmentary atrophy of the skin and genital mucosa may also occur in the absence of ulceration, the loss of pigment being, when present, a very characteristic sign of this disease.

Cutaneous lesions may never occur in the mild disease. In virulent infections, edematous urticaria-like plaques, usually circular but sometimes linear or in rings, occur in the skin, especially on the sides of the body and croup. The swelling may be up to 15 cm in diameter and painless and free of itch. They disappear in a few days and new ones form. There is usually no residuum, but sometimes there are local disturbances of sweating and pigmentation.

Nervous manifestations develop late in the course and usually lead to death. There is acute hyperesthesia initially, which may be generalized or localized to the distribution of particular nerves. Later, there is diminished sensitivity or even anesthesia, and this is accompanied by paresis or paralysis of individual motor nerves. The pareses are either unilateral in distribution or asymmetrical in severity and most commonly involve the facial nerves and the motor nerves of the hindlimbs. Decubitus follows.

The *general manifestations* are chiefly of continued or remittent fever, emaciation, and severe anemia. Noninflammatory synovial effusions, superficial lymphadenopathy, uveitis, and optic atrophy are described.

Apart from changes in the peripheral nerves that are responsible for the paralytic phenomena, pathological changes additional to those that are clinically observable are not reported. Degenerative changes occur chiefly in the lumbar and fifth and seventh cranial nerves, being most severe in the roots and also involving the ganglia. The neuropathy is probably preceded by edematous infiltrations, and these may still be present at death. The large nerve trunks are transformed into fibrous cords that are fused with the surrounding muscular fascia. Microscopically, there is edema, mononuclear infiltration and fibrosis of the perineurium. There is slight endoneural reactivity in fascicles in which there is extensive fiber degeneration. Sclerosing changes are also present in the ganglia.

NEOPLASTIC DISEASES OF THE TUBULAR GENITALIA

Isolated reports have ascribed parentage of both benign and malignant tumors to all histologic components of the tubular genitalia, sometimes with doubtful credentials. Some of the least uncommon tumors warrant brief discussion.

Tumors of the vulva could be discussed with tumors of the skin. *Squamous cell carcinoma* is well known in the mare and cow, and, indeed, a high incidence in cows is reported from Kenya. These bovine cases are analogous to the orbital tumors of cattle, thought to be initiated in a solar dermatosis, their incidence negatively correlated with the degree of local epithelial pigmentation.

Leiomyoma

Leiomyomas are the most common tumors of the tubular genitalia of the bitch. Leiomyomas are less common in other species but, regardless of species, leiomyomas have characteristic gross features. Their origin is from the smooth muscle in the wall of the uterus, cervix, or vagina, and, although they may be solitary, they are usually multiple. The tumor in the bitch is neither malignant nor wholly autonomous, being, in some unknown manner, *endocrine-dependent*. It rarely occurs in the bitch earlier than middle age and is frequently associated with ovarian follicular cysts or estrogen-secreting tumors, and often also with endometrial hyperplasia, mammary hyperplasia, and mammary neoplasia. Bitches castrated early in life are exempt, and established tumors regress following castration. This tumor has been provoked in guinea pigs by continuous low-level doses of estrogen but, for spontaneous leiomyomas as well as endometrial and mammary neoplasms, there is as yet no precise knowledge of the role of estrogen.

The genital leiomyoma may grow to be as large as 10–12 cm in diameter but is not invasive. The smaller tumors are fleshy but, as they enlarge, become firm or hard (hence the clinical term "*fibroid*") due to the connective-tissue stroma. On cut surface, they have a watered-silk appearance and the color, whether more fleshy or white, depends on relative amounts of muscle and connective tissue. Figure 4.150 shows the gross features of a large leiomyoma in the uterus of a cow. The tumor is not encapsulated but is well demarcated and easily shelled out. In almost all cases, the tumors project as globose or elliptical masses or as bulbous polyps into the lumen of the vagina, uterus, or cervix, but some project outward and a few are found in the mesometrium. Figure 4.151 is a photograph of two leiomyomas in the uterus of a bitch. Occasionally large numbers of small leiomyomas are found in the vagina (Fig. 4.152).

Degenerative changes occur in the larger tumors and are of two types: either progressive replacement by fibrous tissue of the stroma, or edema and liquefaction with cyst formation. In the first type, the fibrosis may progress through hyalinization to mineralization. The second type of degenerative change afflicts vaginal leiomyomas especially, probably because these more often become pedunculated and susceptible to circulatory embarrassment.

Histologically, the tumor is composed of whorling bundles of smooth-muscle cells with abundant stroma but scant intercellular connective tissue. The organization does not depart much from normal, and often the presence of neoplasm is best appreciated by the naked-eye appearance of the tissue.

Leiomyosarcoma

Cytologic features, such as pleomorphism, rate of mitoses, and invasiveness, help differentiate leiomyomas from leiomyosarcomas.

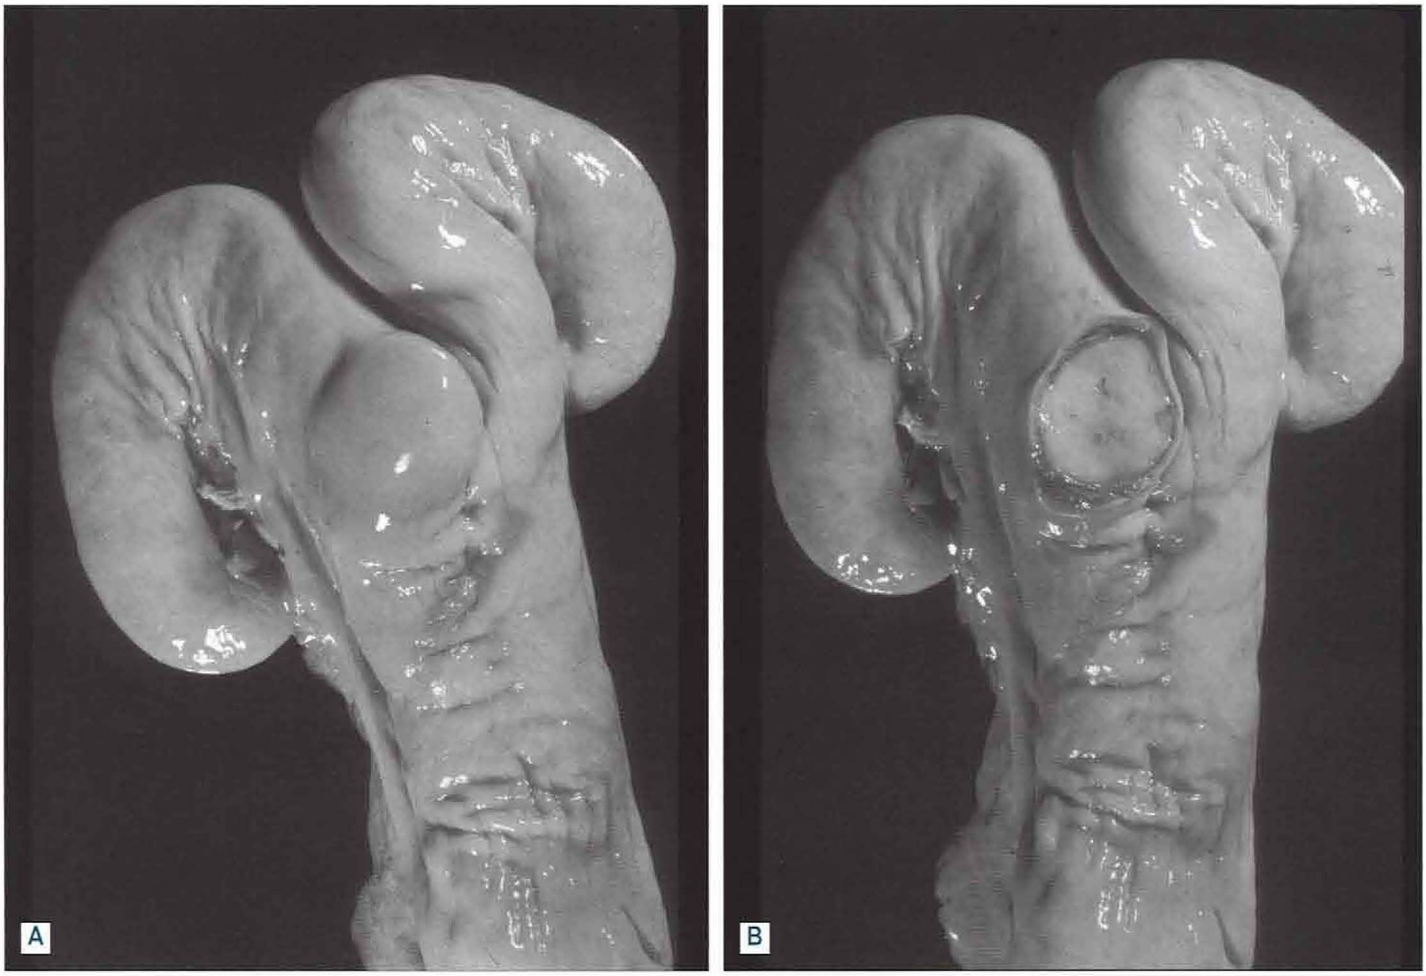

Figure 4.150 **A. Leiomyoma** seen as a single mass in the dorsal wall of the uterus of a cow. **B.** The serosa and myometrium over the mass and outer half of the mass have been removed to reveal the typical firm white appearance of leiomyomas.

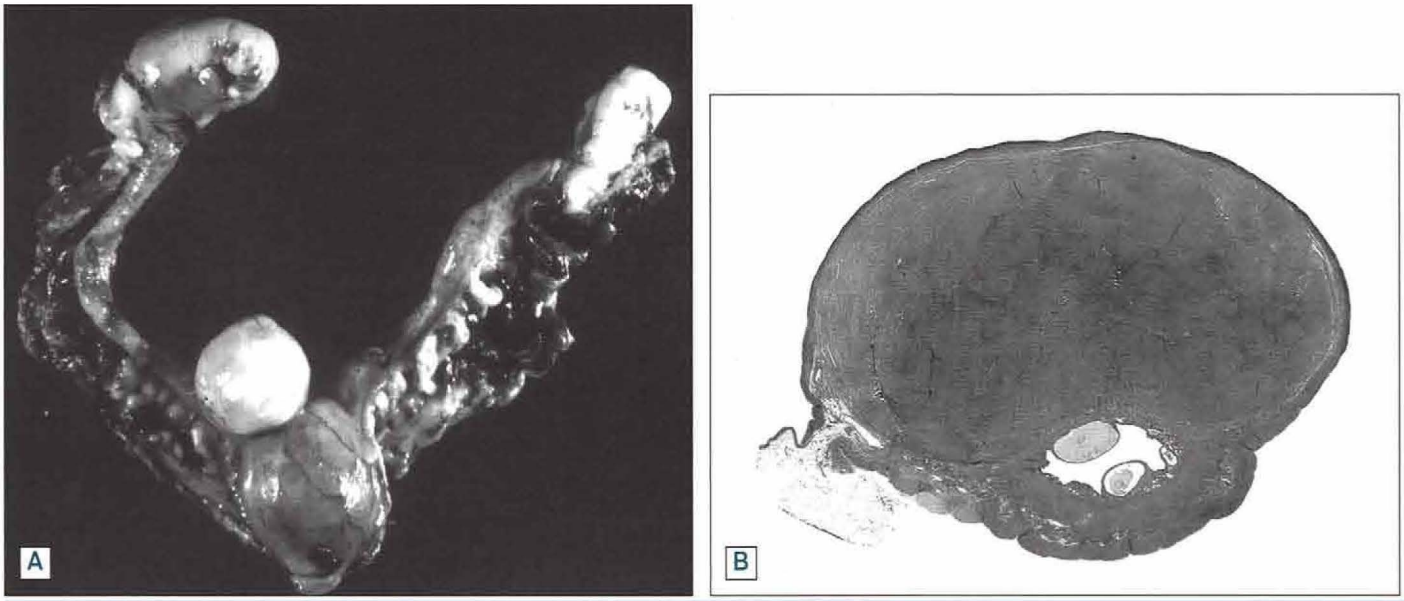

Figure 4.151 **Leiomyomas** can appear as masses within the uterine wall or extend inward or outward. **A.** Two leiomyomas are present in the body of this bitch's uterus, one extending outward from the surface of the base of the uterine horn, and the other filling the lumen of the uterine body. **B.** Subgross section of a uterine leiomyoma from tissues of a different bitch. The tumor is within the wall and has distorted the shape of the uterus. Note the uniform dense nature of the mass. Two endometrial cysts are also present.

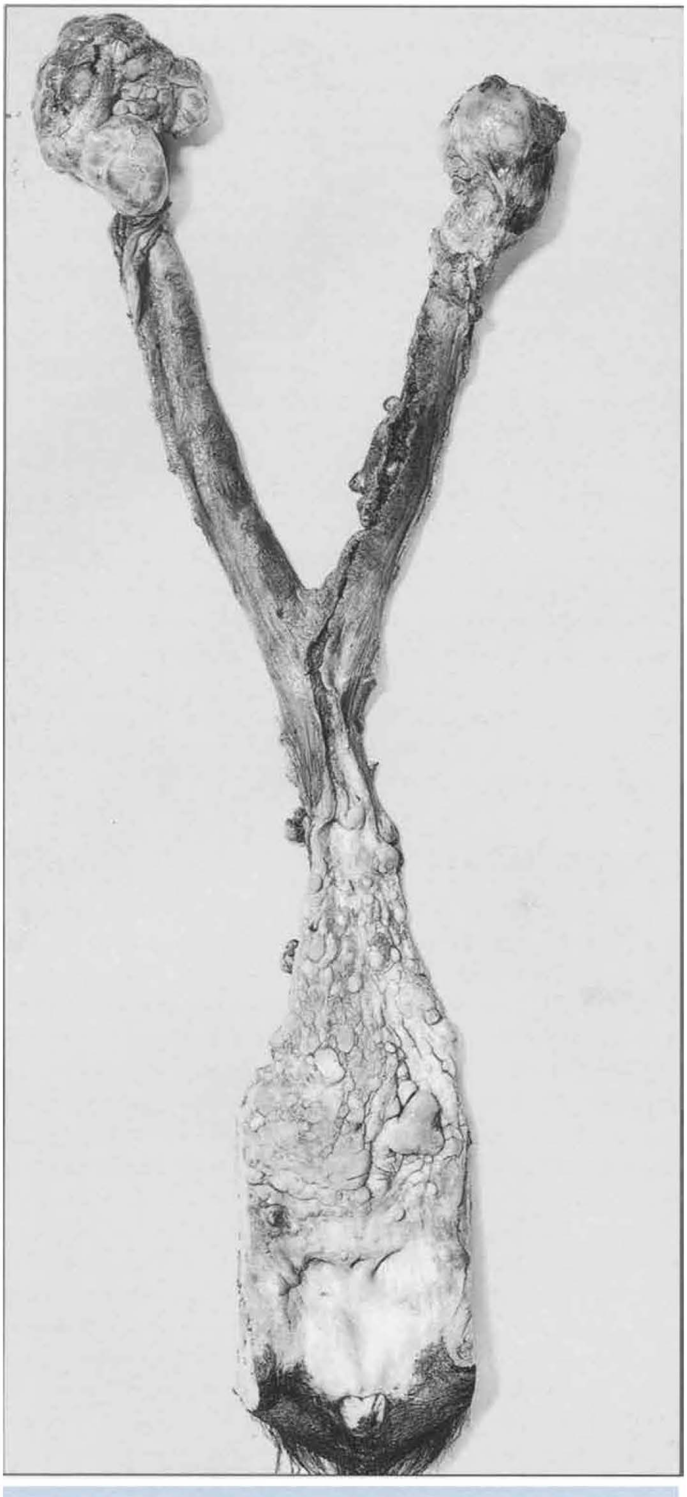

Figure 4.152 Miliary **leiomyosarcoma** involving the vagina of a bitch.

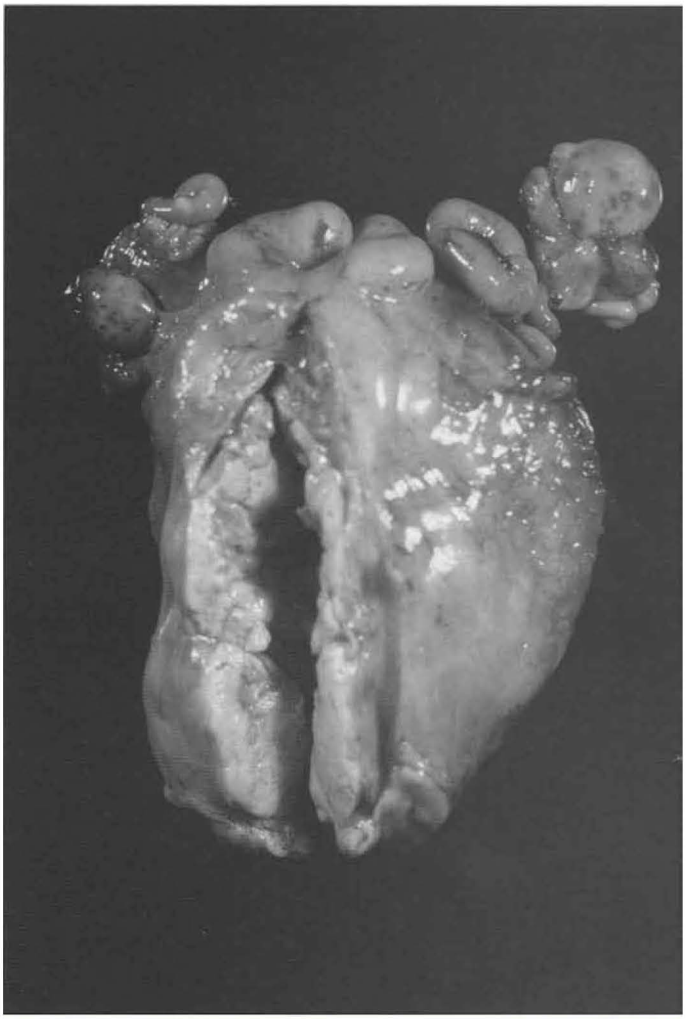

Figure 4.153 Leiomyosarcoma effacing the uterine body, cervix, and cranial vagina in a Saanen goat, which has a predilection for this tumor.

Leiomyosarcomas are *uncommon*, but have been found in older Saanen goats (Fig. 4.153), with occurrence reported in siblings, suggesting that in this breed there may be a genetic defect.

Transmissible venereal tumor of dogs

This tumor is a contagious neoplasm, transmitted most commonly by coitus, and occurs on the external genitalia of either sex. It is also known as Sticker's sarcoma. The noncommittal name of the tumor, transmissible venereal tumor, is preferred to such terms as lymphosarcoma, histiocytoma, and sarcoma, which, suitably prefaced to indicate its transmissibility, have been used. Because the host's tissues do not contribute to the growth, the histogenesis is obscure and likely to remain so. This tumor differs from other infectious tumors in that *the infecting cells are transplanted and grow like a graft.* This was the first neoplasm in the history of pathology to be transmitted experimentally; this was accomplished by the Russian veterinarian Novinsky in 1863.

The tumor has been reported from Europe and Asia as well as from the Americas. There are marked fluctuations in its prevalence in endemic areas over the course of a few years. The tumor tends to be common where dogs are allowed to run free and is rare where dogs are controlled. The tumor is not confined to the genitalia, but in some few cases is found in other cutaneous locations. *Metastasis sometimes occurs to regional lymph nodes, but spontaneous regression usually occurs in less than 6 months.*

It seems unlikely that a tumor of such character would originate in multiple geographic centers; more probably its wide distribution, especially in tropical and subtropical areas, is due to a manner of spread akin to that of infectious disease. This is an assumption

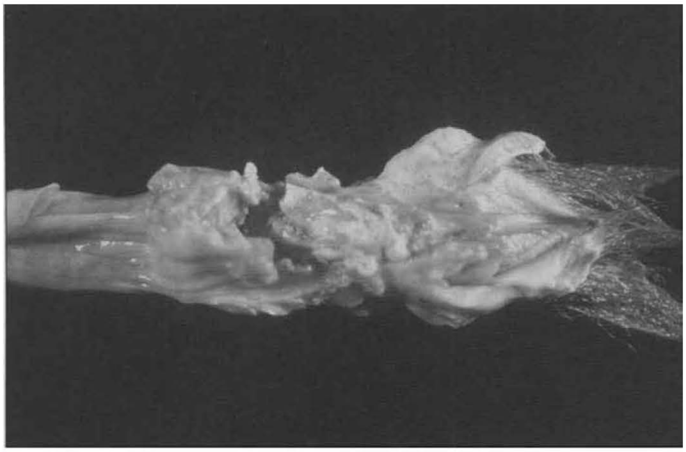

Figure 4.154 Transmissible venereal tumor in the vagina of a bitch. These tumors are transmitted from dog to dog by transplantation of neoplastic cells.

impossible to prove, but it is supported by the fairly constant karyotypes of the tumor cells to the extent that these have been examined. The diploid number of chromosomes in dogs is 78, and, normally, they are acrocentric except for X and Y. The chromosome complement of tumor cells originating in separated areas of Japan and North America is closely similar, most tumor cells containing 59 chromosomes; the minor variations in chromosome numbers in some cells and in chromosome morphology are within the variability accepted for stem-lines of transplantable tumors and long-term cell cultures.

In the vagina, the tumor takes origin in the submucosa, usually of the dorsal wall, as one or more papular or papillary proliferations (Fig. 4.154). Expansive growth also occurs mainly in the submucosa, and the overlying epithelium becomes stretched and attenuated. With rupture or penetration of the epithelium, the tumor projects into the vagina as an irregular, ulcerated, and friable mass that may protrude from the vulva. Histologically, the tumor varies depending on the stage of growth or regression. During the early stage of growth, the tumor is composed of round, oval, or polyhedral cells with indistinct boundaries and poorly stained or clear cytoplasm. The nuclei are large in proportion to cell size with a single, well-defined nucleolus and many chromatin granules. Variability in the size of the cells is rather characteristic and mitoses are frequent. Electron microscopic studies have shown that most cells in growing tumors are round cells with microvilli, whereas regressing tumors have spindle-shaped cells suggestive of tumor cell differentiation toward fibroblastic cells. The number of infiltrating lymphocytes increases as growth of the tumor slows and the tumor begins to regress. Most of the infiltrating lymphocytes are T cells.

In the skin also, the tumor seems to arise in the subcutis, and the epidermis is not usually penetrated. It is suggested that natural cutaneous implantation occurs in bite or other wounds. In any locale, the tumor shows a marked tendency to break down after a few months of rapid progression, and on incision the necrotic tissue resembles pus.

It is not known how this tumor can be transplanted with living cells across major histocompatibility barriers and survive for a substantial time before regressing. Infected dogs do develop antibodies, but in dogs with growing tumors some of these antibodies are blocked by a tumor-associated antigen. This suggests that the expression of this tumor-associated antigen may play a role in blocking systemic immune responses and facilitate tumor growth. Unlike tumor-associated antigen, which is expressed in progressive tumors, class I and class II major histocompatibility antigens are only expressed when regression begins. Dogs are resistant to challenge after natural regression of the tumor. Secondary tumor challenges begin to regress on day 9 and disappear after about 2 weeks. The secondary tumors are rapidly infiltrated by lymphocytes, most of which are T cells, and undergo degeneration. The tumor is transmissible not only between dogs but also to the fox, coyote, and jackal.

The life history of the tumors as outlined above and especially the limited metastatic capability are not constant, and greater contagiousness and more virulent expressions may be expected in immunosuppressed individuals and in a canine population of suboptimal physiologic status. Such appears to be the case, for example, in the promiscuous, scavenging, malnourished, feral populations. There, metastases are common in both sexes as sequelae to the primary lesions. In the female, extension occurs to the uterus, cervix, and uterine tubes. In both sexes, there is early spread to inguinal nodes, which become large and firm. Cutaneous involvement is also common with few or many lesions, some up to 6 cm in diameter, often ulcerated and hemorrhagic. Buccal lesions and large periorbital tumors are also described. Ocular lesions are common in this disease, but, apart from the sites mentioned, conventional metastatic patterns in internal viscera do not occur.

Fibropapilloma of the vulva

This is probably the most common tumor of the bovine vulva and affects young animals primarily. It is, briefly, a wart growing on a mucous membrane, the nature of the host tissue apparently determining the reaction to the virus of bovine verrucae (*Bovine papillomavirus*). This virus infecting the keratinized bovine skin provokes the typical papilloma of relatively scant connective-tissue core and abundant epidermal overgrowth. Transplanted instead to the penile or vulval mucosa, the contribution of the two moieties is reversed, the bulk of the tumor being connective tissue with just enough epithelium to cover it. Histologically, *the bulk of the tumor consists of interlacing bundles of fibrocytes*. In the younger tumors, there may be many mitotic figures, and such cases have often been misdiagnosed as fibrosarcomas. Many of the plump spindle cells have large nuclei with bizarre nucleoli and sometimes pale, eosinophilic inclusion-like intranuclear structures. Collagen formation from the stroma is progressive with duration. Surface ulceration is followed by superficial inflammatory infiltration.

The vulval tumors are usually sessile, rounded growths when young, but become progressively more cauliflower-like. Those attached to the penis are often pedunculated. The natural history of the genital fibropapilloma is the same as that of the common cutaneous papilloma; *spontaneous regression occurs in 1–6 months or so*. Within this period, surgical excision may be followed by recurrence.

Transmissible genital papilloma of the pig

Ordinary cutaneous warts are not described in pigs. A transmissible papilloma occurs in the *preputial diverticulum of the boar*. It is transmissible to the lightly scarified vulval mucosa with an experimental incubation period of about 8 weeks. The lesions are 1–3 cm in size and

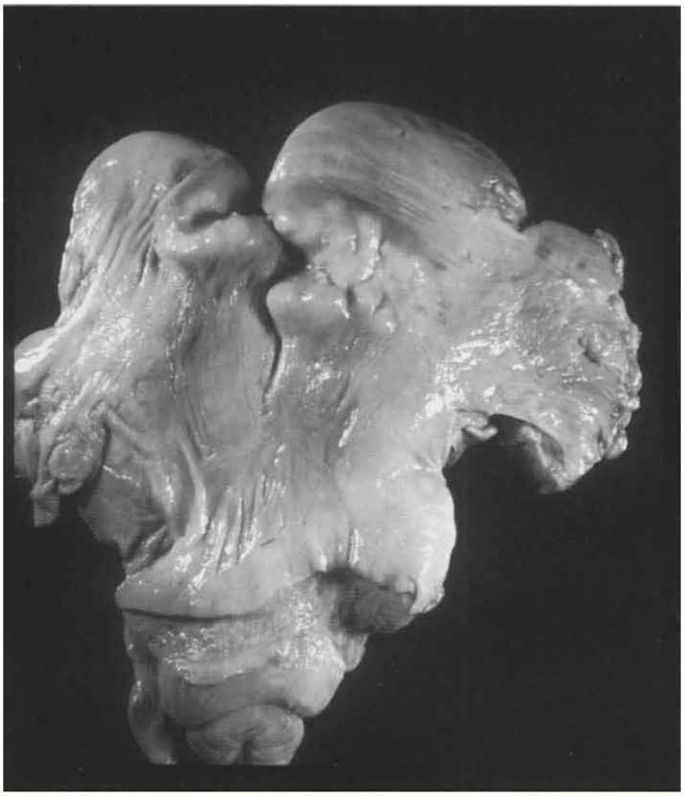

Figure 4.155 Uterine adenocarcinoma in the wall of a uterine horn in a cow. These neoplasms stimulate a marked desmoplastic response, which results in the typical firm, depressed, and contracted appearance of the invading tumor – features that are used to diagnose this tumor grossly.

papular, some of the larger lesions being papillary. The clinical course is not many weeks, after which the lesions begin to regress and are eventually sloughed. Recovered animals are immune to reinfection.

The lesion histologically is typically papillomatous with extensive uneven acanthosis and epithelial overgrowth, but with none of the abundant mesodermal reaction that occurs in the bovine disease outlined above. The broadened malpighian zone contains scattered cells with *intracytoplasmic inclusions* that are large, spherical, homogeneous with acidophilic stains, and often surrounded by a halo. An inflammatory response with mononuclear cell infiltration occurs in the underlying dermis.

Carcinoma of the endometrium and cervix

These are *rare neoplasms* in domestic animals and therein lies their interest. The rarity is real and not, as has been implied, apparent because of inadequate postmortem examination. The most popular current opinion on the pathogenesis of the endometrial carcinomas in women relates them to prolonged estrogenism, with cystic endometrial hyperplasia of the same cause as the precancerous lesion. In domestic animals, on the other hand, cystic endometrial hyperplasia is common but carcinoma is rare and, when it does occur, does not seem to require prior hormonal conditioning of the endometrium.

Carcinoma of the endometrium appears to occur more frequently in *cattle* than in other domestic animals. The tumors may be single or multiple, hard, nodular masses of variable size in the uterine wall. Desmoplastic reaction is commonly a prominent feature, which leads to umbilication of the serosal surface (Fig. 4.155). The regional lymph nodes and the lungs are the usual sites of metastatic lesions.

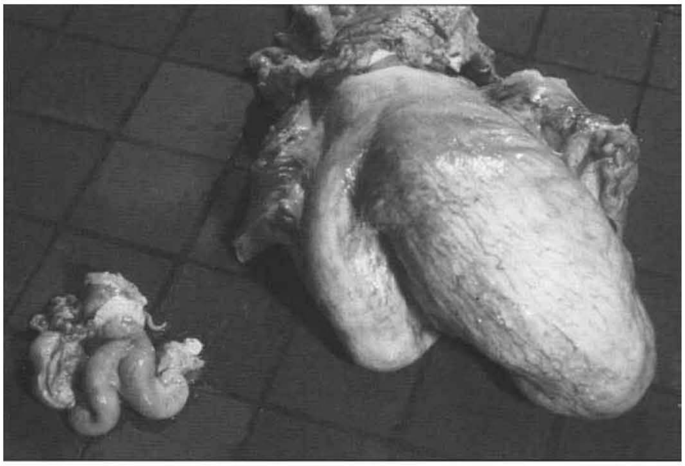

Figure 4.156 Lymphosarcoma diffusely involving the uterus on the right has massively enlarged the uterus. The uterus on the left is from a normal cow.

As noted earlier, focal proliferative lesions of the endometrium and normal or prolonged endometrial repair postdelivery may be confused as being neoplastic changes in the endometrium. This is especially true in the bitch and queen, and caution should be exercised before making a diagnosis of endometrial carcinoma in those species.

Lymphosarcoma

Involvement of the uterus is not uncommon in the multicentric form of *bovine* lymphosarcoma but is distinctly so in other species. As elsewhere, there are two anatomic forms of uterine involvement, diffuse and nodular. In either event, the initial deposition seems to occur in the endometrium. The *diffuse lesion* involves both horns, body, and occasionally the cervix in a more or less uniform thickening, leaving a uterus that can be very large, but retaining its typical shape (Fig. 4.156). The thickened wall loses its elasticity and on cut surface is rather structure-less with an appearance like firm fat (Fig. 4.157). Gentle pressure may expel small quantities of cloudy, highly cellular fluid. There is patchy ulceration of the endometrial mucosa. There is nothing peculiar to the *nodular form* of the disease. These nodules, few or many, may attain large size and cause corresponding deformity. Central liquefactive necrosis is common in them. Microscopically, there is, with either form of the disease, gradual replacement of the normal uterine structures by infiltrating tumor cells. Lesions of corresponding type occur in the vagina, but do so less commonly.

Metastatic tumors

With the exception of lymphosarcoma, secondary neoplastic diseases of the tubular genitalia are rather *rare*. Serosal implantations occur in peritoneal carcinomatosis. There are a few reports of results of immunohistochemical staining of tumors involving either the uterus or ovary in cattle.

Pathology of the mammary glands

The mammary glands are modified cutaneous glands with the important roles of providing nourishment to immature neonates and providing to the newborn of many species passive immunologic protection against pathogenic microbes. The mammary glands may, however, provide a source of infection by microorganisms such as *Mycobacterium paratuberculosis* and the Brucellae, which arrive in the gland hematogenously and provoke minimal pathologic change, or *Pasteurella* spp. and *Streptococcus* spp. during the course of galactogenic infection and inflammation. A number of helminth parasites have adapted their life cycles in ways that ensure their transfer to neonates in milk.

Diseases affecting the skin of the mammary glands and neoplastic diseases, of especial prevalence and importance in dogs and cats are discussed in Vol. 1, Skin and appendages.

DEVELOPMENTAL CONSIDERATIONS

The weight of evidence supports the derivation of mammary glands as specializations from sweat glands. The myoepithelial cells are thought to be of epithelial origin and the relationship to sweat glands possibly accounts for the structural and behavioral similarities, and the participation of myoepithelial cells, of mammary and sweat-gland carcinomas in the bitch.

The glands form on the *mammary line or ridge* detectable in the ventrolateral ectoderm of the embryo. The ectodermal cells of the ridge, which are destined to develop into the mammary glands, congregate in specific areas, of number and location appropriate to the species, to form the *mammary buds*. From the buds, primary sprouts push into the mesenchyme, the number of sprouts from each bud determining the number of openings that will eventually develop in each teat. Only one *primary sprout* develops from each bud in cattle, and is destined to form the *streak canal* and *teat cistern* and, proximally, the *gland cistern*. Secondary sprouts develop from the primary sprout to form the early *milk ducts*. In species such as cattle, sheep, and goats with one teat orifice, the gland is a single large secretory structure. There are usually two streak canals in horses and pigs, 3–7 in the cat, and 8–14 in the dog. In species with multiple teat orifices, a mammary gland is in reality a composite of glands, the number corresponding to the number of streak canals, and each is autonomous and separate from its neighbors.

Supernumerary teats or nipples are common, especially in cattle in which the incidence may reach 30%, and are probably subject to a genetic control mechanism. They occur in males as well as females (except in male horses, which do not develop nipples), and are located in relation to the embryonic mammary ridge, although some may be displaced laterally. In many cases the supernumerary teat will have functional mammary tissue associated with it.

Mammary gland development in *males* is generally similar to that in females in the embryonic and fetal stages. In those species such as rats, mice, and horses, the males of which do not have teats or nipples, the primary sprouts separate from the surface epithelium of the mammary bud under the influence of androgenic hormone and regress. The male mammary gland is susceptible to hormonal stimulation but is not as sensitive as the female. Alveolar structures are not present and the enlargement that occurs under the influence of estrogen is due to cystic ductal hyperplasia. This is most often seen in dogs with estrogen-secreting tumors of the testes.

INFLAMMATORY DISEASE OF THE MAMMARY GLANDS: GENERAL CONSIDERATIONS

Mastitis is inflammation of the mammary gland, and this inflammatory response is nearly always a response to invasion of the gland by one of a number of microbes. The route of invasion may be hematogenous, as

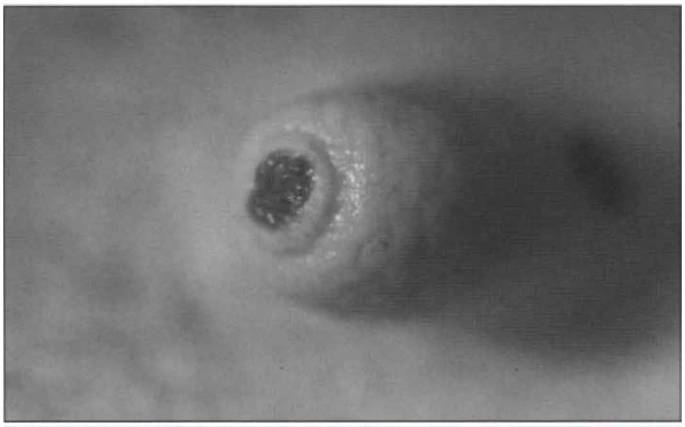

Figure 4.158 Mechanical damage to the teat end from improper milking equipment. The area of the orifice is ulcerated and scabbed, interfering with the barrier function of the streak canal and predisposing to ascending infection. This is a common iatrogenic lesion with important health and economic implications.

in tuberculosis and brucellosis, it may be percutaneous as a complication of local dermatological conditions of the skin or teat, but *the usual route of invasion is through the teat canal.* The relative roles of innate and acquired resistance, damage to the teat sphincter, and factors associated with mechanical milking are complex. The pathogenesis and characteristics of the disease, which are intensively studied only in cows, are dependent on factors in microbial ecology and the nature of the pathogen as well as on host factors.

A primary and critical barrier to infection is the teat canal. The establishment of a bacterial population in the teat cistern is usually followed by inflammation, but the application of even large numbers of bacteria to the teat orifice of an otherwise healthy teat results in infection in only a few cases. The length of the teat canal seems not to be important. Successful defense systems, both innate and acquired, control entry, proliferation, and tissue invasion and involve a spectrum of tissue, cellular, and cytokine responses.

Mechanical injury

Machine milking of dairy cattle is prone to induce significant damage to the teat ends when milking procedures and the milking equipment are not optimal (Fig. 4.158). This damage associated with high vacuum, poor liners, ineffective pulsations, and overmilking leads to partial eversion of the canal, ulceration, and fibrosis with associated bacterial growth (Fig. 4.159). Teat sinus injury from *overmilking* is associated with reduction of the *keratin plug* that helps protect from ascending infections.

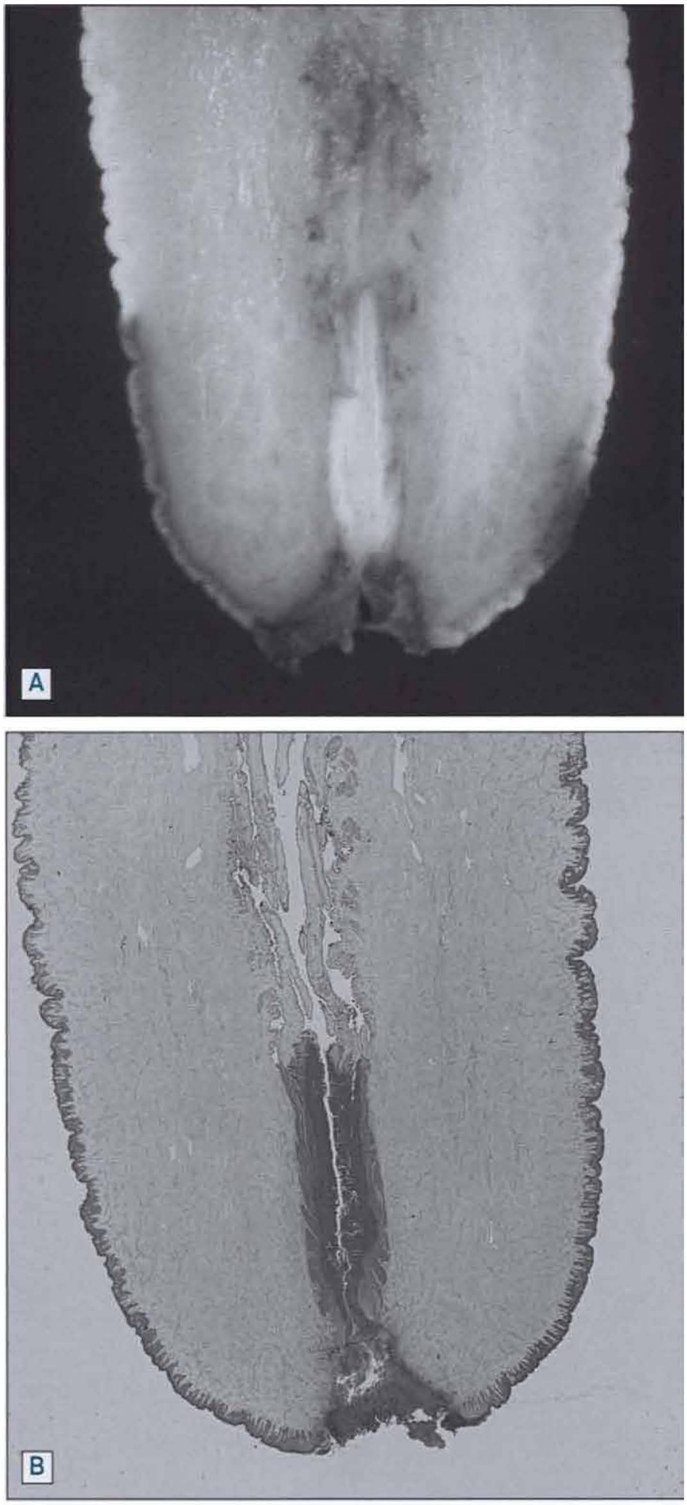

Figure 4.159 A. Sectioned fixed teat shown in Figure 4.158. **B.** Hematoxylin and eosin-stained section showing the teat cistern and keratin-lined teat canal with **focal ulceration** caused by trauma during milking.

INNATE AND ACQUIRED RESISTANCE OF MAMMARY GLANDS

Resistance to mastitis caused by *Streptococcus agalactiae* is rather strong in some cows, so it is possible to compare cows that are highly susceptible with those that are highly resistant. The difference between resistant and susceptible animals is only apparent if the infecting organism is applied to the teat orifice or within the teat canal; disposition of the organism, even in small numbers, within the sinus rather regularly results in infection – apparently the inherited mechanisms of resistance have been bypassed. Resistance is not an all-or-none phenomenon. It declines progressively with age and is, no doubt, subject to the general influence of body health, but at any single exposure to the teat orifice or canal it is all or none. In a susceptible animal, exposure of the canal to even small numbers of the organism is followed by their multiplication and entry into the cistern, whereas, in resistant animals, the inoculated organisms multiply briefly, if at all, in the teat canal, and disappear in the course of 2–3 milkings. *But resistance to this sort of exposure, which most nearly parallels natural exposure, can be removed by removing the smegma of the teat canal.* The teat canal is lined by stratified squamous epithelium that is surfaced by a layer of keratin-like material and then an innermost layer of smegma – a waxy material probably composed of epithelial debris and milk solids. Although the lining of the teat canal is an invagination from the normal surface epithelium, its chemical composition, as judged by staining reactions, is quite different. It is possible that there is in the smegma of the teat orifice of resistant cows some substance that is actually inhibitory to the growth of *S. agalactiae*. The phenomenon of resistance can be demonstrated also to operate in infections by *Staphylococcus aureus*, but with two differences. There is no increasing-with-age susceptibility to staphylococcal infections, and cows that are resistant to *Streptococcus agalactiae* are not necessarily resistant to *Staphylococcus aureus* and vice versa; apparently, the ingredients of resistance to the two infections are not the same.

There are humoral and cellular factors in normal milk that are inhibitory to bacterial growth and that may be increased in inflammation.

Lactoferrin is an iron-binding protein present in secretions and in neutrophils, which is inhibitory to the multiplication of bacteria with high iron requirements. The high concentration of citrate in normal milk prevents the action of lactoferrin, but it is effective in the secretion of the nonlactating gland.

Lysozyme is locally synthesized in the gland and, although the concentration in milk is low, there is some correlation between milk titer and susceptibility to infection. The titer may be increased during inflammation.

Lactoperoxidase is synthesized by mammary epithelium and is potentially inhibitory of *S. aureus* and most streptococci. It is a source of hydrogen peroxide available as a byproduct of bacterial fermentation of milk carbohydrates.

There are differences between species in the nature of **immunoglobulins** in colostrum and milk. In the cow, the immunoglobulins are predominantly of the *IgG* class, and are selectively transferred from serum to milk. The levels are low in normal glands but permeability changes in inflammation allow the titer to be much increased. The same class of antibody is identified with the concentration of plasma cells in the distal teat cistern and proximal streak canal, and may have an effect against organisms resident in the streak canal. *The major role of these antibodies is to promote opsonization of microorganisms. IgA* is also present in milk and may have a defensive effect on bacterial adherence to epithelial surfaces. Gram-negative bacteria can be killed by the *complement-antibody system*. The activity of this system in milk is normally low but can be greatly increased in inflammation as a result of permeability changes in mammary vasculature. There is variation among animals in the level of bacteriocidal activity in serum, but this appears to be the main mechanism limiting the duration of acute coliform infections.

Phagocytosis is the most important component of defense against gram-positive bacteria that have gained entry to the gland. Neutrophils enter the secretion in large numbers during mastitis, but the efficiency of phagocytosis and killing of engulfed bacteria is less in milk than in serum. The reduced efficiency may be due to depletion of energy substrates or lysosomal exhaustion following ingestion of lipid droplets or other solid materials in milk. Nonetheless, leukocytes do have a very significant role in controlling infection and in preventing superimposed infections in inflamed glands.

BOVINE MASTITIS

Bovine mastitis is typically a response to ascending infection of the gland by way of the teat canal. In spite of diligent efforts to limit infective opportunities and to treat established infections, the incidence of the disease and of reinfection is, overall, not much changed. The problems appear to reside in limited defense against colonization by ascending infection and in clearing mechanisms of limited effectiveness.

Potential mammary pathogens are ubiquitous. Modern techniques of microbial classification have identified more than 100 species, subspecies, and serovars isolated from the mammary gland. *Streptococcus agalactiae and perhaps some types of Staphylococcus aureus are obligate parasites of the gland and inevitable pathogens, but the great majority of infections are opportunistic.* It is perhaps useful to view the mammary gland and its microbiota in the same way as the bacterial colonization of other epithelial surfaces is viewed, whereby the local epithelial microenvironment is available for colonization by competent microbes. In this view, the consistent presence of *Corynebacterium bovis* and coagulase-negative staphylococci as well as other ill-characterized microaerophilic and anaerobic organisms reflects the *normal ecology* on which from time to time populations of other microorganisms may be superimposed.

Mastitis, excepting that caused by obligate pathogens, might best be regarded as an *inflammatory disease rather than an infectious disease*, and is one expressed by tissue injury when the microbial balance is upset and becomes dominated by organisms that are injurious by virtue of tissue invasiveness or toxigenicity. The pathologic process may range from transient to persistent and from mild or subclinical to peracute and fatal.

Notwithstanding the large number of microbial species that may be isolated from the diseased mammary gland, *the epidemiological picture of bovine mastitis is dominated by the streptococci, staphylococci, and coliforms.* Some infections, such as by *Cryptococcus* and the atypical mycobacteria, are usually iatrogenic. Some infections, such as by *Pseudomonas* and *Prototheca*, reflect heavy environmental contamination. Once the inflammatory process is established, additional microbial species, particularly the anaerobes, may participate by permission of a changed intramammary environment, allowing growth of resident organisms or altered competence of the teat canal, allowing entry of additional species.

Streptococcal mastitis

Bacteria of the family Streptococcaceae are important causes of bovine mastitis. *Streptococcus agalactiae, S. dysgalactiae,* and *S. uberis* are the most frequently implicated. Sporadic disease has been associated with *S. equi* and its subspecies *zooepidemicus, S. bovis, S, pyogenes, S. pneumoniae, Enterococcus faecalis, E. faecium,* and *E. durans.*

Bovine mastitis due to *Streptococcus agalactiae* was by far the most common and important of the forms of bovine mastitis until it was subdued by therapy. *The causative agent has the mammary gland of the cow and goat as its natural and sole habitat*; resistance to the extramammary environment is low, although the organism may survive for a month or more on fomites, but environmental factors are important in the transfer of infection from cow to cow.

The only significant portal of entry of *S. agalactiae* into the mammary gland is through the teat canal. Mastitis is always a possible complication of traumatic teat injuries, but infection in such cases is more often due to environmental organisms than to *S. agalactiae.*

Streptococcal mastitis is usually permanent. The organism is capable of maintaining its numbers in the cisterns in opposition to inflammatory products and the irrigative force of milking. How it remains in equilibrium with its host in the infection phase is not clear. At a variable period following the establishment of infection, the bacterial population may suddenly increase and the tissue becomes invaded for a brief period producing a clinical crisis. This proliferation of bacteria within the cisterns precedes tissue penetration and is associated with altered virulence of the organism, as measured by mouse-pathogenicity tests. Whether there is also some change in the host system is not known, but change ought perhaps to be expected, because the detrimental effects of improper machine milking, in terms of height of vacuum, rate of pulsation, and period of application, are expressions, largely, of flare-ups of established quiescent infections. Repeated invasions usher in a series of inflammatory and reparative reactions, which, if unchecked therapeutically, culminate in fibrosis and involution of the affected quarter.

There are various degrees of severity of the clinical reaction of streptococcal mastitis, the more acute cases being associated with systemic disturbances and the less acute ones not. The anatomic basis lies not in the acuteness of the inflammation, but in the amount of mammary tissue involved. A greater or lesser amount of normal uninflamed tissue is always present, the inflammatory reaction being confined to those areas in which the organisms manage to penetrate the duct epithelium. It appears that the streptococci are unable to penetrate the interstitial tissues to a significant degree, although sometimes they are found in leukocytes in the lymphatics and supramammary lymph node, and that the inflammatory reaction is due to diffusing toxic products of the organisms. This period of epithelial penetration is brief, being of only a few hours' duration, and the organism in tissue is rapidly destroyed by leukocytes. This destruction of the organism may at times sterilize the udder or so diminish numbers that bacterial cultures of milk taken during a crisis may be negative, a finding that also applies to other acute mammary infections.

The first response to the penetration of streptococci is remarkable interstitial edema and extensive migration of neutrophils into the interlobular tissue and secretory acini. Stromal lymphatics are widely dilated and contain numerous leukocytes that are delivered to the regional lymph node. The acinar epithelium becomes vacuolated and desquamated, or in places heaped up and ragged, over accumulations of macrophages and fibroblasts that make their appearance very early in the course of the reaction. Streptococci are very numerous at this stage, both within the ducts and acini and in and under the epithelium. *The acute exudative reaction gives way to two processes that proceed together – pathologic fibrosis and involution.* A few organisms still persist in the larger ducts and the neutrophil reaction is reduced, but macrophages and fibroblasts continue to increase in number (Fig. 4.160A) and eventually obliterate many of the acini. Lymphocytic

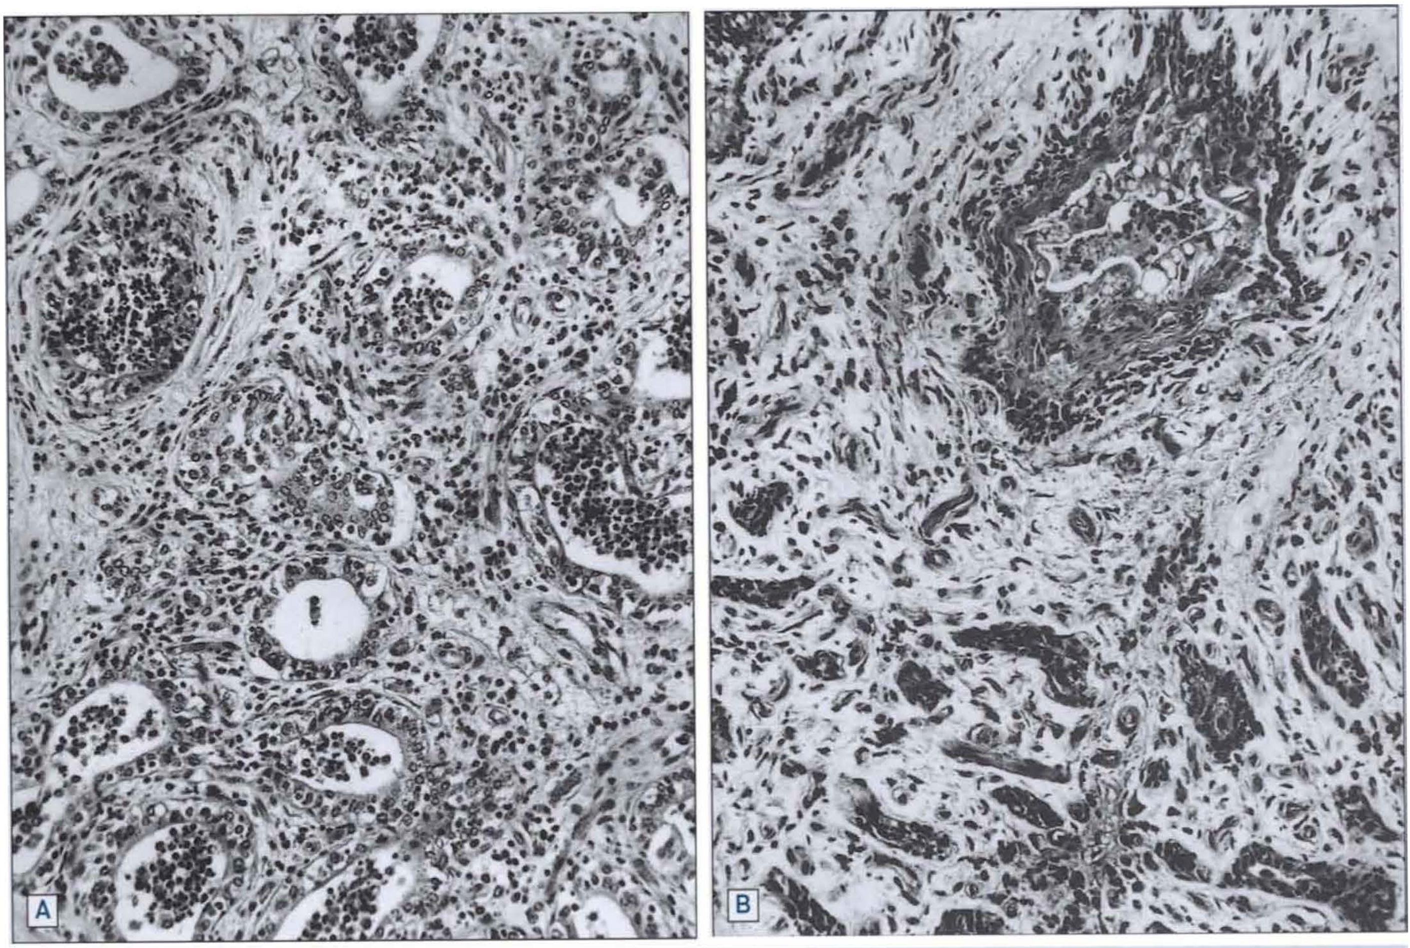

Figure 4.160 A. Acute streptococcal mastitis in a cow. **B. Chronic streptococcal mastitis** is characterized by fibrosis, atrophy of the glandular secretory epithelium, and squamous metaplasia of the ducts.

foci begin to develop in the interstitial tissue. Other acini become dilated and rounded and contain a stringy coagulum with intact cells and cellular debris, which constitutes the first indications of the involution that follows interruption of secretion and acinar stagnation.

The involution affects lobules directly involved in the exudative inflammation as well as those surrounded by interacinar tissue to which the fibroplasia has extended. Stagnation of secretion also occurs in many of the smaller ducts. It is pertinent to note that this is the stage that on palpation is swollen, firm, and painful and often referred to as "fibrosed." But there is as yet little fibrosis, *"induration" being due instead to retained secretion.* These nodular or diffuse indurations are firm and liver-like in consistency but of normal color and are easily cut, in contrast to the normal slack elasticity of mammary tissue that makes it difficult to cut. The processes of fibrosis and involution continue until the end-stages, when some lobules show normally involuted tissue, some are obliterated by fibrosis (Fig. 4.160B), and others show a variable balance between both processes. Such a gland is atrophic, dry, and, because of the fibrosis, poorly elastic. Some lobules escape for a time, often a long time, only to be involved ultimately in a flare-up or by extension of the disease process. It is evident then that the many lobules involved are often out of phase with each other, but that in each the succession of events proceeds rapidly.

Adjacent to the spots where the streptococci invade the epithelium of the smaller ducts, *granulation tissue develops rapidly and exuberantly and protrudes into the duct lumen*, which is dilated and contains stagnant milk, exudate, and numerous organisms. These polypoid proliferations may completely obstruct the duct or, by fusing with the opposite surface, produce loculations resembling abscess cavities that are clearly visible macroscopically. There is concomitant proliferation of periductal fibrous tissue spreading centrifugally to involve and obliterate large amounts of lobular tissue. Such granulation tissue in time cicatrizes and the duct epithelium is restored. Similar changes occur in the larger ducts and teat cisterns at points of bacterial penetration, but they are less exuberant and the epithelium is shortly transformed to a squamous, sometimes keratinizing, type that is later desquamated and reconstituted as the acute phase subsides to the chronic one of involution and as fibrosis supervenes. *Involution has been regarded as a defense mechanism, but this misconstrues its purely passive development as a consequence of stagnation.* Such involuted lobules are capable of function at subsequent lactations. Whether there is any replacement of destroyed lobules by regeneration from persistent ducts has not been established, but it cannot amount to much.

The *gross appearances* of streptococcal mastitis vary according to the stage of the disease. Usually more than one quarter is involved, but not uniformly, most of the change taking place in the distal portion of the gland about the cisterns and large ducts. The cisterns and ducts are filled with secretion in the early stage of the disease, the secretion being serous and floccular, or distinctly purulent. The mucous membrane of the cistern may not be appreciably altered or it may be hyperemic and granular. The glandular tissue is swollen and turgid. It cuts easily with a knife, and on the cut surface the lobulations are distinct because the swollen lobules protrude. It is not possible to recognize the interstitial edema. The affected lobular tissue is gray and can be distinguished from the milky whiteness of normal lactating tissue, but not readily from involuted parenchyma.

In the later stages of the disease, the most obvious changes occur in the cisterns and large ducts as moderate thickening of the epithelium and small rounded polypoid proliferations into the lumen of the cistern and large ducts. Fibrosis is recognizable in these cases surrounding the ducts, surrounding lobules and obliterating some, and diminishing in severity towards the base of the gland.

Infection with ***Streptococcus uberis***, an environmental pathogen, may produce transient inflammation, often accompanied by systemic signs of illness, and infection may become persistent. Infection tends to be sporadic, but occasionally there are severe outbreaks in individual herds. Mammary gland infection with *S. uberis* is recognized as one of the least well-controlled causes of mastitis in dairy cattle. Any of *S. agalactiae, S. dysgalactiae,* and *S. uberis* may be present with *Arcanobacterium pyogenes* in the severe summer mastitis of dry cows and heifers.

Mastitis caused by ***S. pyogenes*** is of some importance because the organism is a human pathogen; the secretion from infected quarters may contain enormous numbers of these organisms, but they proliferate barely, if at all, in drawn samples of milk. The mammary infections may arise from close association with infected humans, and outbreaks of upper-airway infection have occurred in people consuming milk from infected cows.

Staphylococcal mastitis

Staphylococcal mastitis is predominantly an infection of the younger age groups, and there is no increase in susceptibility with age.

Pathogenic strains of staphylococci are always of human or animal origin and persist as permanent inhabitants of the skin and mucous membranes, although they are capable of more than average resistance to the general environment. It is generally accepted that the infection of the udder is *contagious*, and it seems probable that entry through the teat canal is, in general, subject to the same sort of local controls as is the entry of *S. agalactiae*.

Pathogenic staphylococci can be broadly grouped as to whether they are catalase-positive or catalase-negative. The ability of a strain to produce catalase and hemolysis is the best single criterion of pathogenicity for animals. The coagulase-positive staphylococci include the important ***Staphylococcus aureus***, as well as *S. intermedius* and *S. hyicus*. The coagulase-negative staphylococci comprise a large number of species, of which *S. epidermidis* is the species most frequently isolated from milk. These species are of low pathogenicity and may perhaps be best regarded as part of the normal flora. They are commonly recovered from normal milk samples and from cases of subclinical mastitis expressed as elevated somatic cell counts in drawn samples.

Mastitis paralleling the natural disease can be produced by infusing the udder with the α toxin; the β toxin is nonirritant. Strains of the organism, not separable by other criteria, differ in their toxigenicity, but this is not necessarily related to pathogenicity; one strain may produce gangrenous mastitis on some occasions and only a mild disease on other occasions.

Clinically, staphylococcal mastitis may be peracute and fulminating or milder and more chronic; the latter is the more common. The acute forms of the disease, typically, occur shortly after parturition and tend to produce gangrene of affected quarters and high mortality. The affected quarters are swollen and tense, hot and firm, and very painful. There is almost complete stagnation of secretion and only a few milliliters of brown, blood-stained, or straw-colored watery fluid can be expressed from the teat. Uninfected quarters of the same udder are also swollen and tense and the secretion is reduced but otherwise normal – an effect probably due to the diffusion of toxins through the vascular bed of the gland.

Gangrene usually affects first the teat and adjacent portions of the udder and may not be more extensive, or it may extend even to involve the whole quarter. The tissues become blue and eventually black and are softer, insensitive, and cold. There is pitting edema of the inguinal area, flank, and venter, and in a day or so the necrotic skin begins to exude serum and to slough, and crepitating gas bubbles develop beneath it. The changes are those of ordinary moist gangrene remarkable only for the abundance of fluid exudation, and attributable to the direct action of toxin on the acinar tissue and to venous thrombosis. The amount of tissue involved in the gangrenous process is quite variable and groups of necrotic lobules adjoin others that are near normal. Natural separation of the gangrenous areas begins about a week after the onset but proceeds slowly with the development of a suppurative surface and fistulae.

The acute, nongangrenous, and mild forms of the disease progress more closely along the lines already described for streptococcal mastitis, but with some important differences that will be mentioned later. It appears that early events are comparable to those of streptococcal infection and that the bacterial population, resident in the ducts and cisterns during the infection phase, multiplies rapidly (Fig. 4.161A) and then penetrates the duct wall to the interacinar tissue. If the penetration is massive and the organisms are highly toxigenic, the acute and gangrenous forms of the disease occur. But the invasion, even if massive, is only massive in patches and intervening areas remain normal for some time (Fig. 4.161B).

The differences in the manner of progression of streptococcal and the milder staphylococcal mastitis depend on different toxigenicity of the genera and the ability of the staphylococci to invade more deeply into the interacinar tissue and to establish themselves there as persistent foci of infection to provoke the granulomatous reaction known as "*botryomycosis*" (Fig. 4.162).

The initial reaction is necrotizing and these necrotic foci are soon surrounded by an intense leukocytic response, and fibroplasia develops rapidly to wall off the irritant foci, thus obliterating large portions of the normal mammary structure. Each granulomatous focus may be no more than 1–2 cm in diameter, but they may be numerous and involve a large proportion of the gland with, between them, a residuum of involuted lobules that is surrounded by septa greatly thickened by confluence of fibrosis. The thickened septa and the granulomas are readily visible to the naked eye and small amounts of pus can be expressed from them. Microscopically, the granulomas closely resemble those of actinomycosis and have been so called, but the coccal organisms are easily visible in the microabscesses. Walled off by connective tissue, the bacteria are not exposed to the action of antibiotics. The infection is always a localized one, and even in peracute cases bacteremia does not occur.

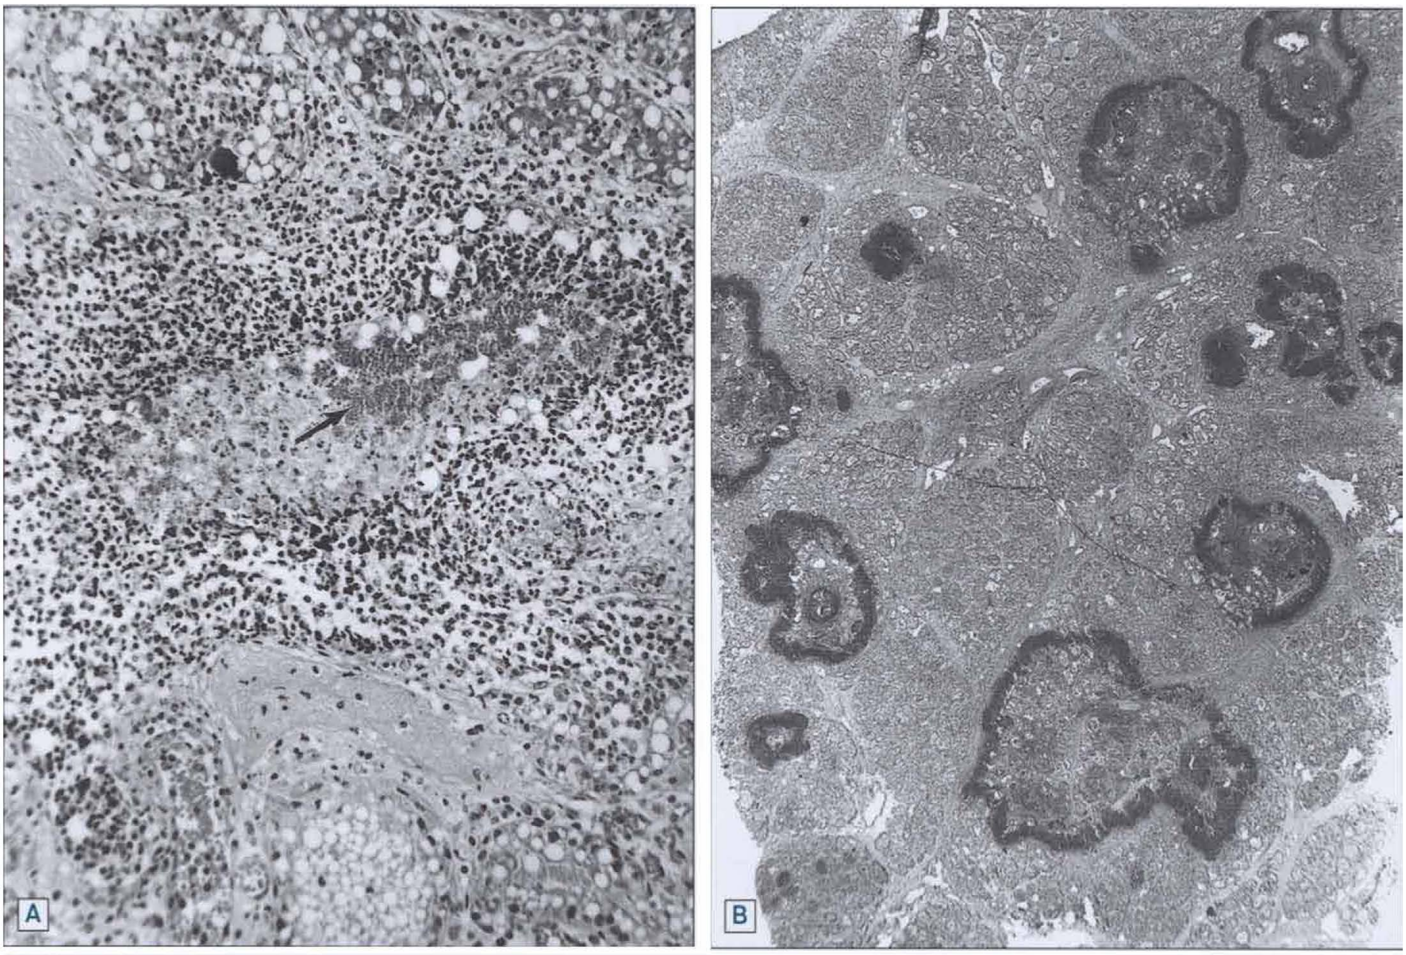

Figure 4.161 A. Acute staphylococcal mastitis in a cow, with bacterial colonies present. **B.** Multifocal areas of locally extensive **acute necrotizing mastitis** in staphylococcal mastitis.

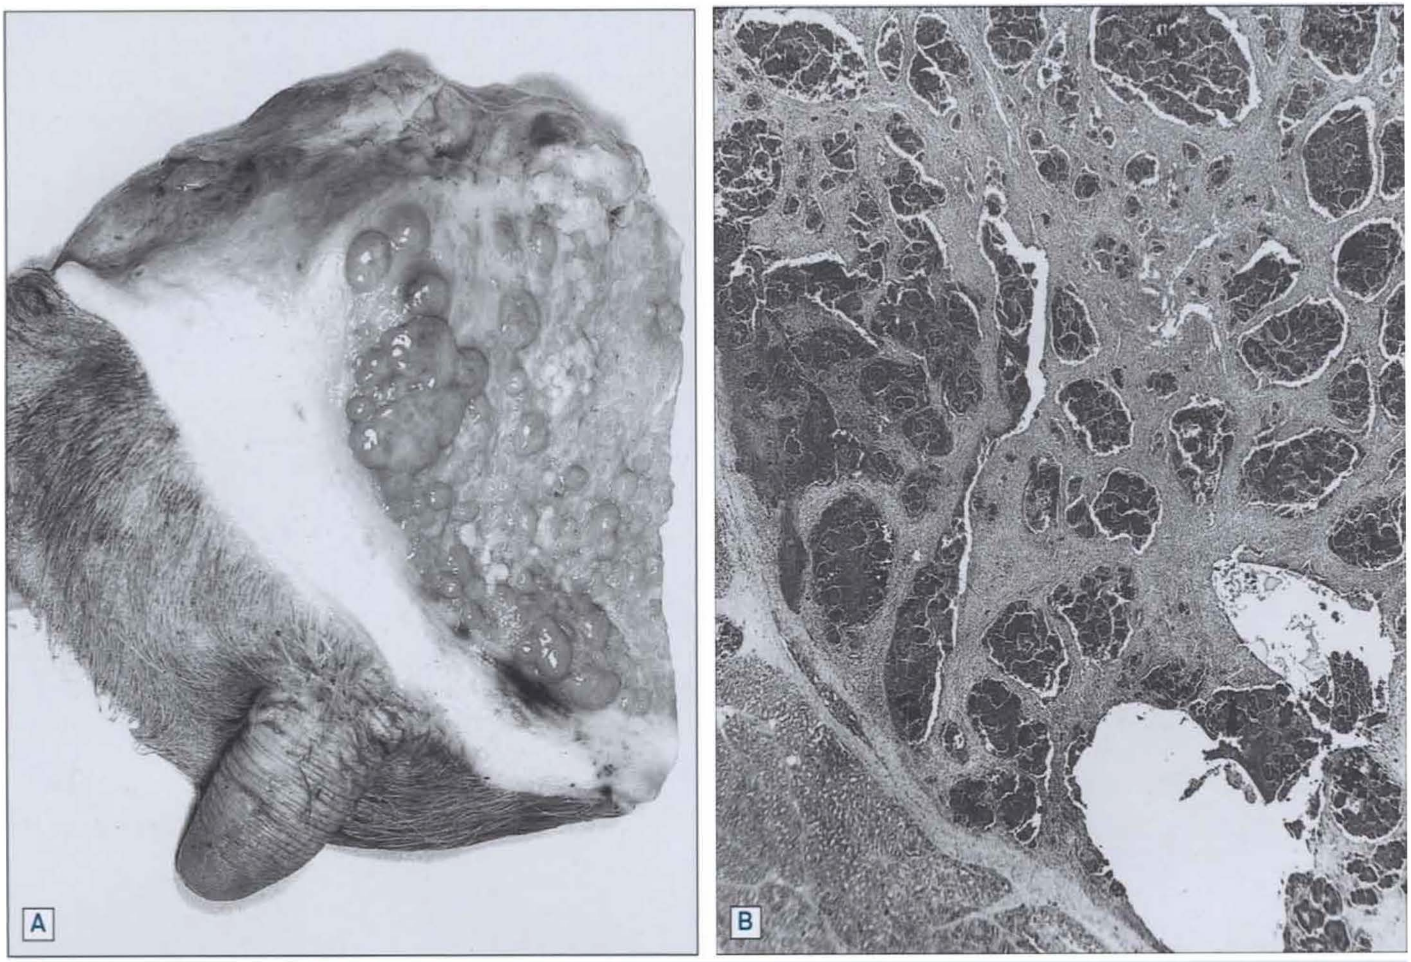

Figure 4.162 A. Multifocal granulomas with associated fibrosis in **chronic staphylococcal mastitis** in a cow; referred to as a **botryomycotic type**. **B.** Photomicrograph of the lesion in **(A)**. Note the thick bands of fibrous connective tissue.

The organ changes in glands shedding nonhemolytic, coagulase-negative staphylococci of low pathogenicity without clinical signs of infection are mild progressive fibrosis and lobular atrophy. Hemolytic coagulase-positive staphylococci produced lobular lesions of greater extent and rate of progression. The different stages of the inflammatory reaction in different lobules is quite like that in the streptococcal disease, and the patchy progression corresponds to the irregular distribution of cultivable organisms in affected glands. It is proper to emphasize the importance in this mild disease of partial or complete occlusion of small collecting ducts or intralobular ducts by exudate or granulation tissue as mechanisms inducing acinar atrophy. Occluded ducts also produce a locus for bacterial persistence and growth leading to small abscesses and obliterative granulomas.

Staphylococcus epidermidis is an intramammary pathogen, but not a serious one. Infections tend to be eliminated spontaneously.

Coliform mastitis

Coliform bacteria are more common and important than their treatment as a miscellany suggests, but very little is known of the pathogenesis and lesions. The bacteria usually grouped in this category include ***Escherichia coli*** and species of the genera ***Enterobacter, Klebsiella, Citrobacter, Serratia,*** and ***Proteus***. *These organisms are part of the* **environmental** *flora, and they do not have a particular predilection for the mammary gland; mammary infection may be correlated with the level of environmental exposure.* Each usually produces a clinically acute form of the disease with systemic reaction and, especially in the case of *Escherichia coli, septicemia*. Acute tendovaginitis may also occur. Both *E. coli* and *Enterobacter aerogenes* may be associated with clinical flare-ups of the milder progressive type of disease with a history closely resembling that caused by *Streptococcus agalactiae*. With these infections also, negative cultures may be obtained during the acute phase.

Coliform mastitis is a serious problems in herds in which the more common mammary infections are suppressed or eliminated. *Coliform mastitis can be viewed as a disease of a normal lactating gland,* the microbe being ineffectual in initiating infection in glands that, as a result of prior irritation, produce large numbers of neutrophils in the secretion. Coliform bacteria are ubiquitous in the dairy environment and microbial density may be enormously increased by well-intentioned husbandry procedures.

In accord with convention, *the mammary changes produced by coliform organisms are attributed to the action of endotoxins.* Cellular susceptibility to the actions of endotoxins are of course important, but the tissue changes that dominate the response are the result of endotoxic injury to the microvasculature of the alveolar walls and

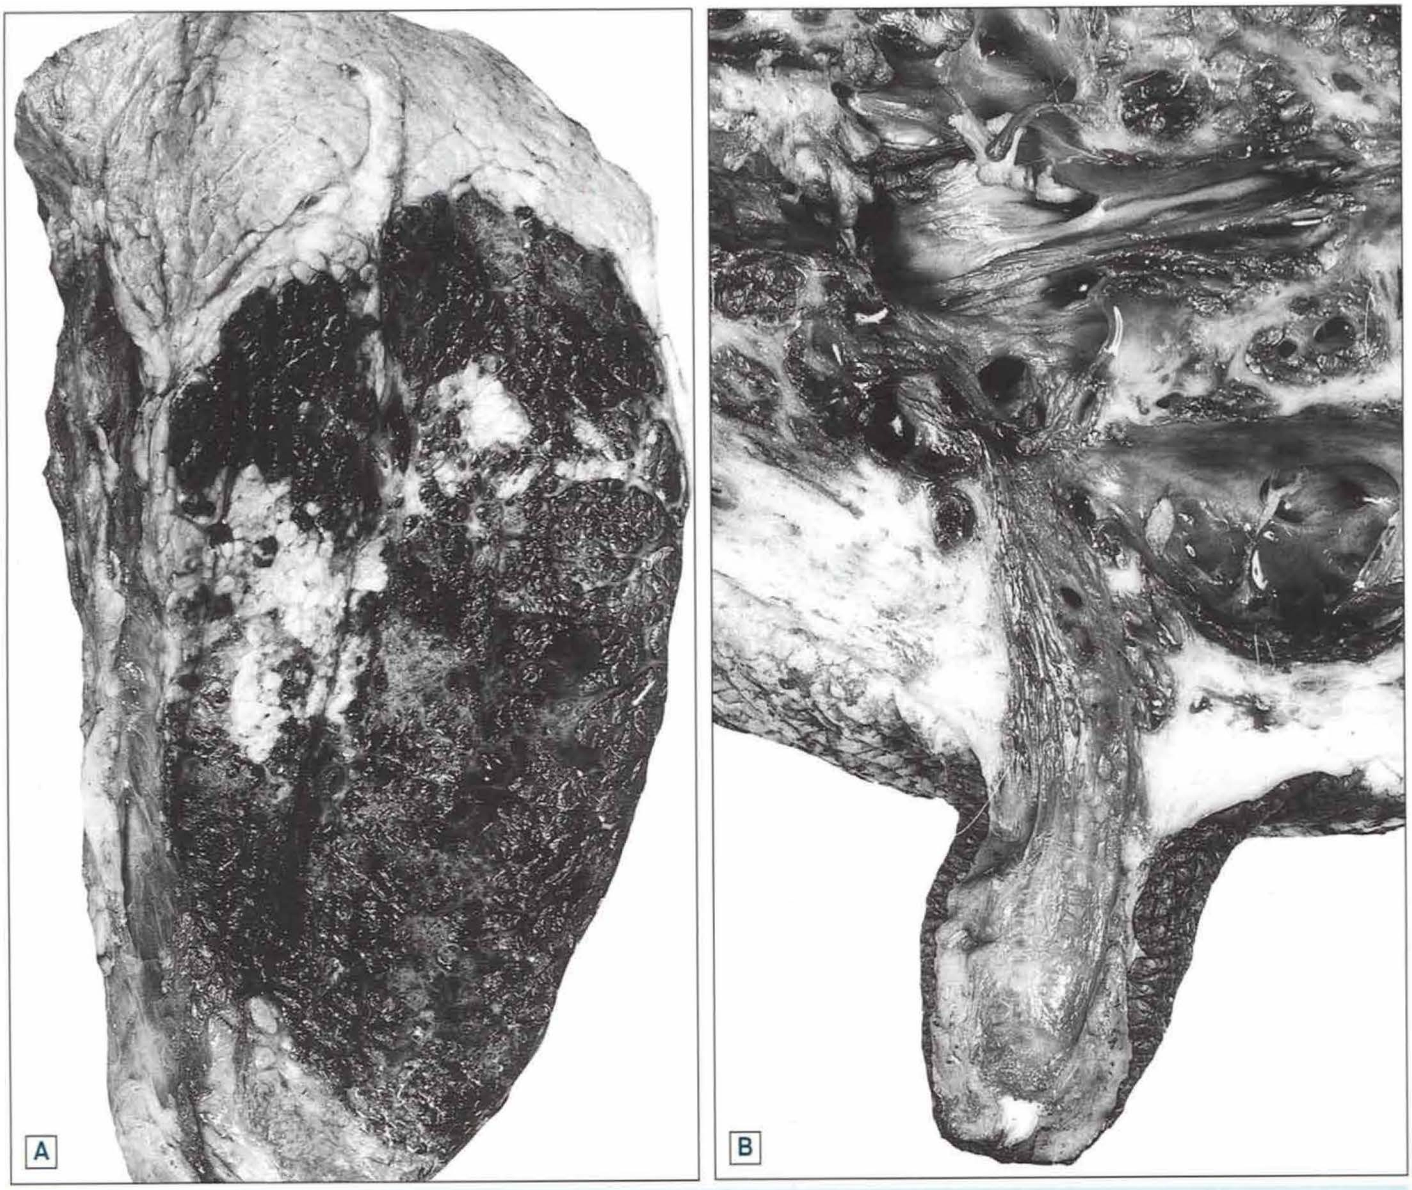

Figure 4.163 Coliform mastitis. **A.** Acute locally extensive hemorrhagic necrotizing mastitis. **B.** Hemorrhagic purulent **galactophoritis**.

mammary interstitium. Acute infections that provoke massive neutrophil release may be self-cleansing. Chronic infections do however occur, characterized by irregular exacerbations, but the mechanisms of persistent infection are unclear and may be related to the adequacy of host responses and the sensitivity of the bacteria to the lytic effects of the antibody/complement mechanism.

The pathology of the coliform infections has not been studied in detail. Indeed, there is even some debate on the pathogenesis of those infections produced by the enterobacteria, a hematogenous route of infection frequently being postulated because mastitis often coexists with puerperal infection of the uterus. *It appears much more likely that infection is galactogenic*, because the cisterns and ducts bear the brunt of the injury and contain numerous bacteria whereas neither bacteria nor significant leukocytosis can be demonstrated in the interstitial tissue in the peracute infections, which are the fatal ones.

The infection is often limited to one quarter and, being of short course, the inflammation may be predominantly serous with much edema, or it may be severely hemorrhagic (Fig. 4.163A). The secretion in the cistern is scanty and may be watery, or cloudy and blood-stained; it contains floccules of fibrin and coagulated casein. Similar floccules can often be seen as plugs in the milk ducts (Fig. 4.163B). There is usually severe edema of the subcutis.

Microscopically, the inflammatory reaction is seen to be centered on the ducts. The lining of the larger ducts is destroyed and replaced by fibrinocellular exudate. The lining of the smaller, intralobular ducts is also destroyed and in these there are plugs of necrotic detritus (Fig. 4.164).

The acini are filled with serous fluid in which there are vacuolated desquamated epithelial cells, but leukocytes are few or absent, either in the alveoli or in the septa. The septal tissues, especially the interlobular septa, are widened by edema fluid, and the greatly dilated lymphatics contain many plugs of fibrin. In areas of hemorrhagic inflammation, the septal vessels are suffused with blood and tortuous and there is extensive hemorrhage into the stroma and into the acini.

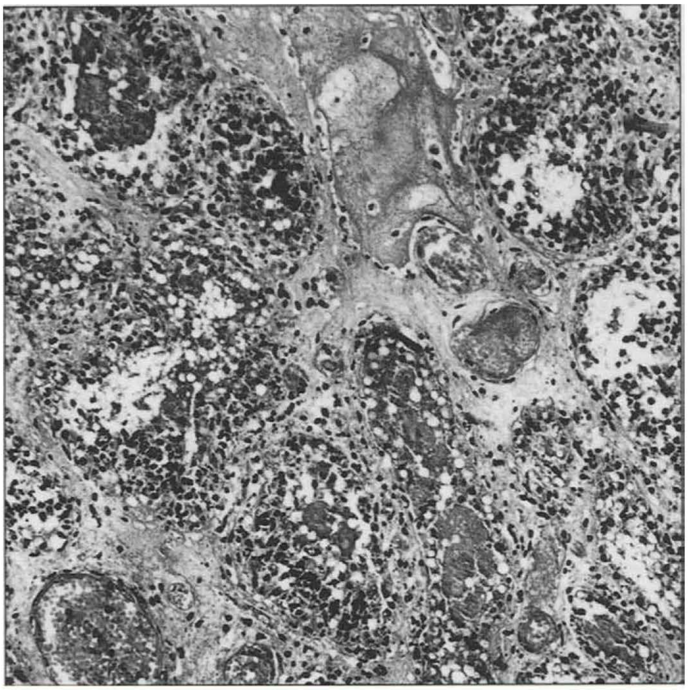

Figure 4.164 Acute fibrinous necrotizing mastitis, in bovine coliform mastitis.

If the course of the peracute inflammation is prolonged beyond 1–2 days, *extensive necrosis of tissue may occur*. Gangrene is not produced by coliform bacilli alone. The necrosis is evident by the altered stainability of the tissues; the histoarchitecture of the tissue is retained for some time. If the animal survives, the necrotic tissue, usually most of one quarter, is sequestrated.

Summer mastitis

Arcanobacterium (formerly *Actinomyces, Corynebacterium*) ***pyogenes*** causes sporadic cases of acute mastitis as a result of penetrating injury and is frequently associated with a form of mammary disease known in the UK as summer mastitis and in continental Europe as Holstein udder plague. *This is usually a mixed bacterial infection affecting immature and nonlactating glands of animals at pasture.* While *Arcanobacterium pyogenes* can cause sporadic cases of suppurative mastitis and can be experimentally transmitted via the teat canal, it cannot always be recovered from the exudates of summer mastitis. It is more usual to recover a mixture of organisms that may include *A. pyogenes, Streptococcus dysgalactiae, Peptostreptococcus indolicus, Bacteroides melaninogenicus, Fusobacterium necrophorum,* microaerophilic, and unidentified obligate anaerobes. Infection is acquired via the teat canal, probably as a result of contamination by flies attracted to pre-existing teat lesions such as impetigo, papular stomatitis, trauma, and photosensitization.

The sequence of events in actinomycotic mastitis has not been studied, but the lesion is clearly a *necrotizing suppurative galactophoritis* with slight primary involvement of the acinar tissue. Grossly visible abscesses form where the exudate remains stagnant in the ducts. The smaller abscesses occur in the intralobular ducts, and these are associated with desquamative changes and the exudation of a few leukocytes into the acini, and with rapid fibroplasia and infiltration of leukocytes, including many plasma cells, in the septa. The smaller intralobular abscesses may heal with obliteration of the ducts and scarification of the lobule. The large abscesses are centered on the larger ducts, the walls of which are remodeled by exuberant granulation tissue, although still lined in part by hyperplastic and squamous epithelium. Bacteria are numerous in the abscesses and in the secretions in other parts of the duct system. The walls of the teat canal and cistern are thickened by granulation tissue and the mucosa is ragged. The cistern is narrowed by fibrosis, and the teat canal may be stenotic or atretic.

Mycoplasma mastitis

The mycoplasmas are difficult organisms to handle, and much sorting out of them remains to be done in terms of their classification, ecology, and pathogenic capabilities. They are prominent causes of bovine mastitis. In herds where sincere attempts are made to control mammary infections, their presence is suggested by high attack rates, rapid spread to other quarters and within the herd, unrewarded efforts to culture bacteria, and very poor response to therapy. Shedding of the organisms from infected quarters is inconsistent, adding to the challenge of clinical diagnosis and control.

The diseases produced by *Mycoplasma* spp. and *Acholeplasma* are not clearly separable pathologically or clinically. The following discussion relates in particular to ***Mycoplasma bovis*** which, being the most frequent of these infections, is used here as the type infection, although infections by *M. canadense, M. bovigenitalium,* and *M. californicum* are also common.

The disease is characterized by *sudden onset of agalactia*. The mammary gland is initially swollen, firm, and painless. Ordinarily there are no systemic signs, but arthritis may complicate some outbreaks. When clinical signs are more extravagant, coexisting mammary infections should be suspected. The disease spreads rapidly in a herd, and animals in full lactation tend to be affected simultaneously in all glands. The milk as drawn appears normal but rapidly forms a floccular deposit and clear supernatant on standing. The presence of pus or blood probably indicates coexistent bacterial infection, although the mycoplasmas do cause massive emigration of neutrophils.

Affected quarters are, in the active stages, swollen and firm but later become slack as rapid involution occurs. The altered secretion and glandular enlargement may persist for several weeks. Clinical recovery may occur without return to full normal function, and such animals may continue to excrete the organism intermittently for more than a year. It is not clear whether clinical relapses occur or whether over this long period there is cumulative mammary injury.

The route of infection of the mammary gland is not clear. The disease can be produced experimentally, usually in an acute form, by applying the organisms on the teat or within the canal, as well as by intravenous injection. The mode of spread suggests a galactopoietic infection, but the occurrence of arthritis suggests that systemic dissemination occurs in some cases.

The pathological changes in the gland appear fairly distinguishable from other causative types of mastitis, and the available descriptions of tissue changes have much in common. *The distinguishing features appear to be the abundant exudation of granulocytes in the early stages, and the hyperplasia of alveolar as well as ductal epithelium in later stages.*

The exudation of granulocytes begins within a few hours of experimental infection as perivascular accumulations in walls of the cistern, in the lobular interstitium, which is edematous, and mixed

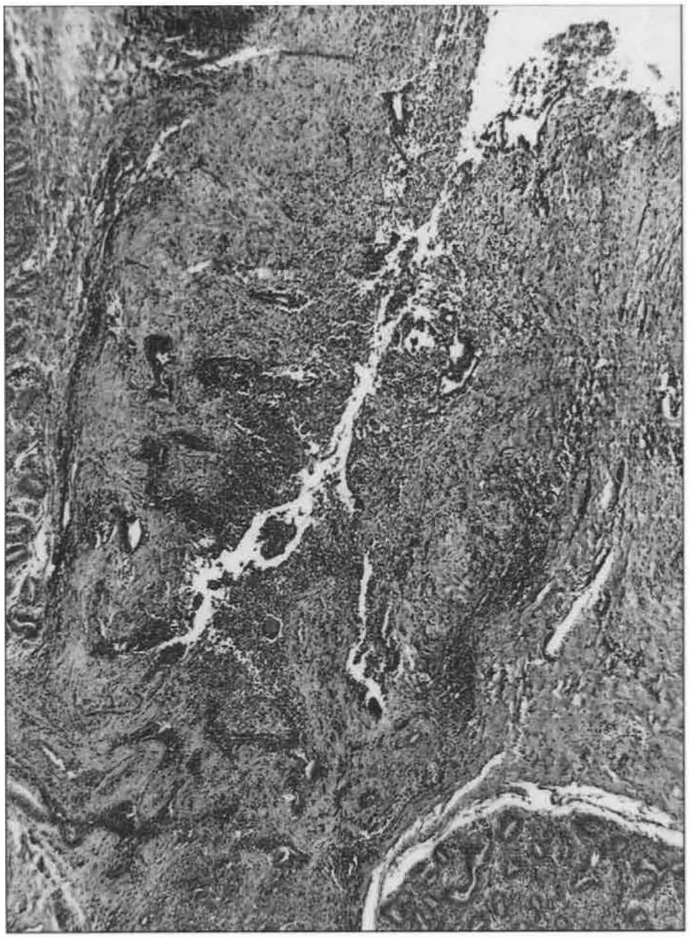

Figure 4.165 Chronic granulomatous galactophoritis, in bovine tuberculosis.

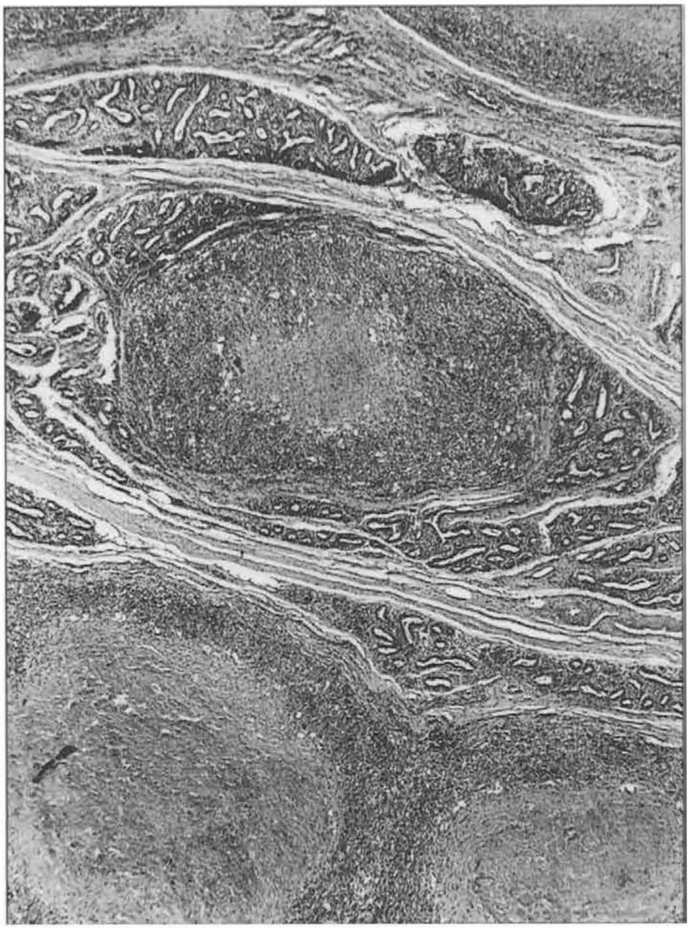

Figure 4.166 Multifocal (miliary) **tuberculous mastitis** in a cow.

with the alveolar secretion. Initially patchy, the reaction extends quickly to involve most of the parenchyma, and, after several days, the reaction begins to subside; mononuclear cells, including plasma cells and macrophages, appear in the exudates; and dense focal lymphocytic accumulations develop in intralobular and periductal connective tissue. The lymphocytic infiltrations persist for many months. The epithelial cells of alveoli and ducts develop large fat vacuoles that are discharged into the lumen. The alveolar epithelium shortly becomes hyperplastic, the rather undifferentiated cells being present in several layers. In the course of some weeks, fibrosis of intralobular septa is accompanied by alveolar atrophy. Hyperplastic and metaplastic alterations also occur in the ductal epithelium, around which is progressive fibroplasia and lymphocytic infiltration. There is extensive but discontinuous erosion of the epithelium, and similar changes occur in the epithelium of the milk cistern. Exuberant granulation tissue forms, especially at the sites of epithelial erosion, producing polypous protrusions into the ducts and cistern. Retention of exudate occurs in small ducts. The exudate tends to mineralize and serve as a nidus for discrete granulomas.

Bovine tuberculous mastitis

Various figures have been quoted for the incidence of mastitis in bovine tuberculosis, but no satisfactory estimation has so far been made. The most significant generalization is that involvement of the mammary glands is second only to that of the lungs. Its public health importance, however, depends on the observation that, in all cases, regardless of age or activity of the lesion, the ducts are involved and, therefore, every case of mammary tuberculosis is an open case.

There are three major anatomical forms of mammary tuberculosis; *disseminated miliary tuberculosis, chronic organ tuberculosis,* and *caseous tuberculous mastitis*. In the great majority of cases, the infection is blood-borne, with subsequent spread along the ducts (Fig. 4.165). The anatomic form of the lesions is deductively explained on the basis of degrees of resistance and hypersensitivity, but these are essentially imprecise (see Vol. 2, Respiratory system). The disease may occur with outstanding duct involvement following infusion with material contaminated with ***Mycobacterium bovis***.

Disseminated miliary tuberculosis develops as part of an early generalization and is not common, even in a highly infected community. The lesions are rather like those of miliary tuberculosis elsewhere, occurring as nodules up to 1 cm or so in diameter which project above the cut surface. The *tubercles* are not evenly distributed, but rather tend to occur in groups in the deeper tissues. *Some are caseous, others are caseous and mineralized, and all are of typical tubercle structure, often with very heavy capsules*. The foci begin to develop in the interacinar connective tissue and remain localized to lobules that are completely destroyed (Fig. 4.166), but there is no direct progression between adjacent lobules or encroachment on the interlobular connective tissue. The reaction is typically tuberculous, and often there is more than one tubercle in each lobule affected. The interlobular ducts are also extensively involved and the dilated lumen is filled with cellular exudate. The wall itself is greatly increased in thickness by tuberculous granulation tissue and epithelial hyperplasia. The *supramammary lymph nodes* in such cases usually contain many typical tubercles.

Chronic organ tuberculosis *is the most common form, representing 80–90% of cases.* It is rather different from the ordinary tuberculous lesion, and the *regional lymph nodes are not usually involved,* although some may show numerous microscopic foci of infection with few organisms. The mammary tissue is very firm and cuts readily. The lobulated structure is exaggerated and, when cut, projects above the surface of the organ, giving a smoothly bumpy appearance surrounded by the indentation of the interlobular tissue. The lobules that are affected – and most of them tend to be – vary from gray-red to white, and the surface is dry. The lesions begin as one or more foci of granulation tissue within the lobules and they expand and coalesce to involve the entire lobule. A few of them break down and caseate. Histologically, the lobular outlines are retained and the interlobular septa are not involved. The process begins in the intralobular septa, and the diffuse tuberculous granulation tissue overruns and obliterates the acinar tissue. *Typical tubercules do not form,* although the types of cells involved in the reaction are as usual. The intra- and interlobular ducts are always involved and the walls are greatly thickened by granulation tissue. The surface tends to caseate, although some epithelium, altered to a squamous type, may persist. Caseous exudate collects in the sinuses. In this form of the disease, *intramammary spread is entirely by way of the ducts,* and the reaction is typical of any chronic organ tuberculosis and of exogenous or endogenous reinfection in an animal highly resistant by virtue of previous exposure.

Caseous tuberculous mastitis causes great enlargement of affected glands, and they are not nodular. The caseous areas are large and irregular, with the dry yellow caseous appearance and hyperemic margin suggestive of ischemic infarction. Other portions of the gland may show areas of chronic organ tuberculosis, often with commencing caseation and transformation to the diffuse type. Confluence is the rule and there is no limitation of spread by interlobular boundaries. The histological change is characterized by inflammatory exudation of fibrin and numerous leukocytes. The caseated areas are surrounded by a zone of hyperemic granulation tissue of the sort that occurs in chronic organ tuberculosis, and hemorrhage in it occurs frequently. This form of the disease appears to develop from chronic organ tuberculosis, or possibly as part of an early generalization of the disease, in animals whose resistance is lowered by nonspecific factors or in which a high degree of sensitivity to the organism has developed.

There is, in addition, a form of mammary tuberculosis in which the process centers on the interlobular ducts with subsequent spread to the larger ducts. In all cases of tuberculous mastitis there is duct involvement, but in the types already described duct involvement is by spread from initial foci in the intralobular tissues. In this last form, so-called **tuberculous galactophoritis**, there may be no discoverable acinar lesion, or, if the lesions are present, they are more recent than, and obviously derived from, the duct infection. The glandular tissue in such cases retains its lobular character. The ducts are dilated and filled with an exudate of mixed inflammatory cells. The duct epithelium undergoes patchy squamous or keratinizing metaplasia and the walls are greatly thickened by granulation tissue and infiltrated mononuclear cells but have few or no tubercles. *The infectious process apparently begins in the walls of the larger interlobular ducts and extends up and down the duct system.* Proximal progression leads to involvement of the smaller interlobular ducts and their obstruction, and this is followed by involution of the associated lobules. Tubercles occur in the supramammary lymph gland in this form of the disease.

Mammary tuberculosis usually develops insidiously without signs of acute inflammation, except in a few cases of the diffuse caseous type. The gland progressively increases in size and firmness. Rather importantly, *the milk may be physically normal for a long period after the onset of the disease, even though it contains the bacilli.* In the later stages of the disease there is a reduction in the amount of the secretion, and it is converted to a thin whey-like fluid that contains floccules of caseous exudate and very large numbers of bacilli. Because of the predominance of duct involvement, all cases are "open" and bacilli may be passed in the milk before gross lesions of tuberculosis are evident.

Miscellaneous infections

Included within this grouping are bacteria (*Nocardia asteroides, Mycobacterium* spp.), fungi (*Cryptococcus neoformans*), yeasts (*Candida* spp.), and algae (*Prototheca zopfii*). With the exception of *N. asteroides*, these infections develop after infusion of the udder with compounds, usually penicillin, suspended in oil and tend, therefore, to involve a number of animals in individual herds.

Mastitis caused by ***Nocardia asteroides*** (primarily a pathogen of humans and dog) is sporadic, although occasionally it reaches significant proportions in a herd. The source of infection is predominantly the soil, and under unknown circumstances entry is gained to the udder via the teat canal. Although perhaps best regarded as a sporadic infection of individual quarters, it is possible the outbreaks in herds could have resulted from repeated mammary infusions for the control of mastitis.

N. asteroides may be present in mammary secretions for many months without causing clinical signs of mastitis. In other cases, the response to infection is a mild chronic involvement of the mammary gland, while in yet other cases, the reaction is of acute onset and severe clinical course. Severe reactions seem particularly likely to occur in infections acquired near the time of parturition. The severe reactions are characterized by fever that may last for several weeks with other signs of systemic illness, and spread of infection to supramammary nodes and lungs has been demonstrated in some of these cases. Affected quarters enlarge rapidly and in one week may be very firm from fibrosis. In some cases, there is a palpable nodularity, the nodules being 2–5 cm in diameter. These may be small sinus tracts discharging on to the skin, or larger defects that qualify as ruptures. The acute infections may be purulent in small foci, but larger abscesses suggest a mixed infection with *Pseudomonas aeruginosa, Arcanobacterium pyogenes*, or other organisms.

The mastitis is essentially lobular, with the ducts bearing the brunt of the injury. The lining of the ducts and sinuses is thick and corrugated. The drawn milk may be near normal or grossly altered, and in the early stages of infection may contain small white granules up to 1 mm in size, which are tangled masses of bacteria. Similar colonies may be found in the discharge of sinus tracts. The glandular lesions remain fairly restricted to lobules without much coalescence across interlobular septa, except in virulent infections or those with much suppuration. The cut surface of the tissues shows extensive fibrosis

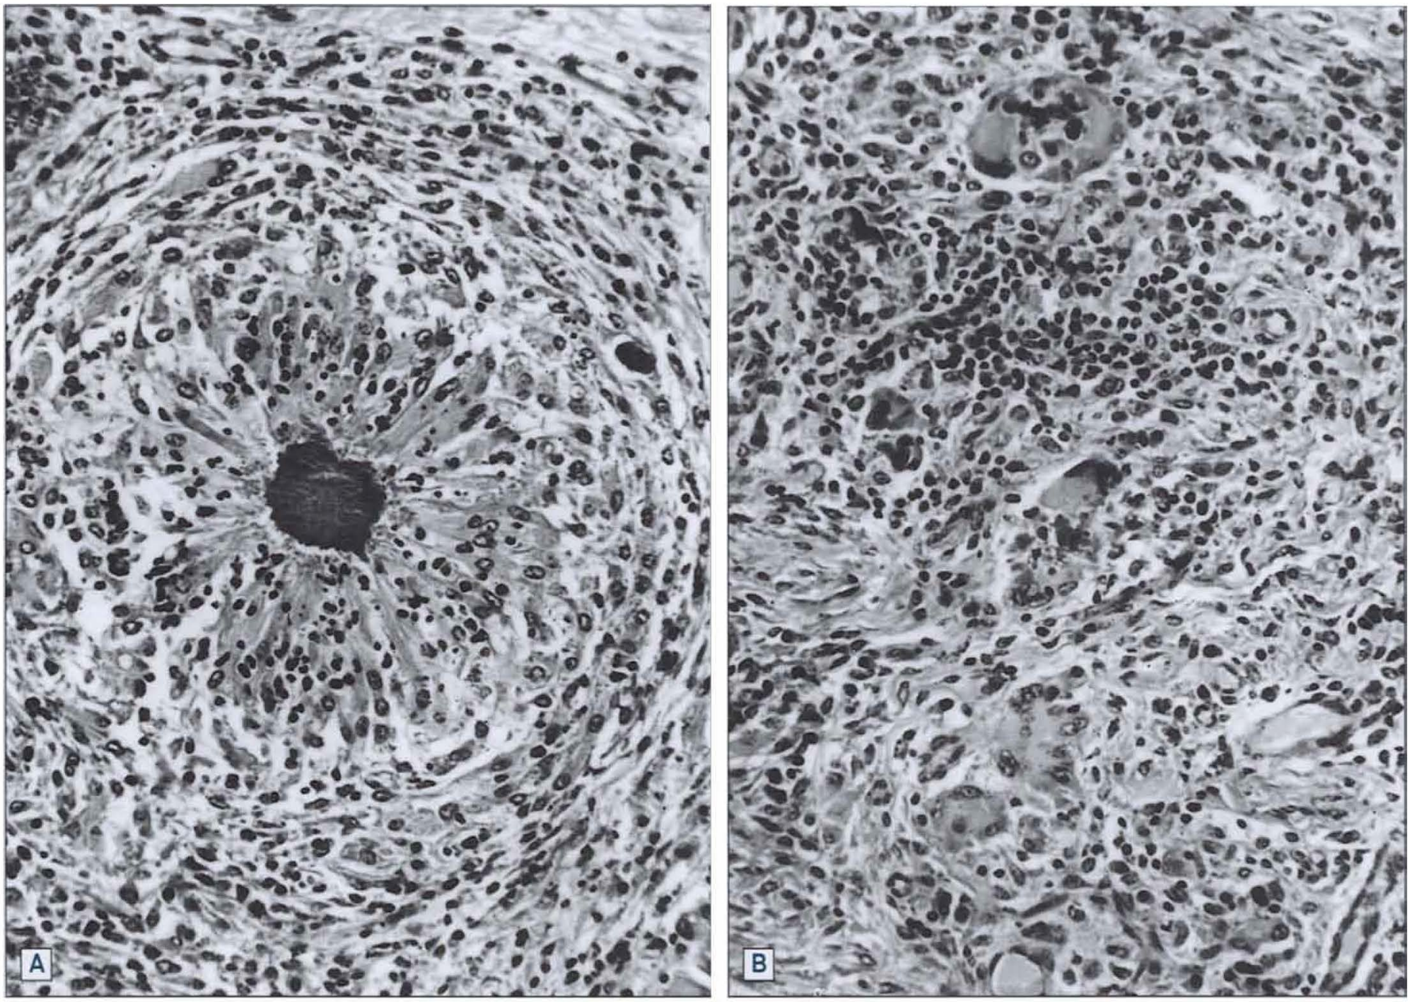

Figure 4.167 Severe **granulomatous mastitis** in bovine mammary tissue, due to *Nocardia*. **A.** Note the **bacterial colony** in the center of the granuloma. **B. Giant cells** predominate in the inflammatory reaction in this field.

and a lumpy lobular appearance that may be beset with small abscesses. The process from there is typically granulomatous without club formation (Fig. 4.167).

Cryptococcal mastitis caused by *Cryptococcus neoformans* has, in most reported instances, followed repeated udder infusion, usually with aqueous or oily penicillin. There is usually involvement of more than one quarter with, in the acute stages, rather severe swelling and increased firmness of the gland, and subcutaneous edema that when chronic produces tight adhesion of the skin to the gland. Changes in the milk occur after 2–3 weeks, when it becomes watery and flaky, although large numbers of organisms are excreted during the acute phase. The diseased tissue is abnormally fleshy, firm, and gray-white with spotty hemorrhages. Lobulation is exaggerated in the acute stages and the cut surface is very slimy with viscid gray secretion that makes the gland hard to handle. Later the tissues become involuted and gray and contain numerous small granulomas.

The histological picture is variable. *In severely affected areas there tends to be complete liquefaction affecting epithelial cells*, and the acini therefore become distended and confined only by the skeleton of connective tissue (Fig. 4.168). The organism is present in very large numbers, and sometimes even the connective tissue is lysed to produce multilocular cystic acini. Thus far the inflammatory reaction is minor, but there develops a massive histiocytic response. Large vacuolated histiocytes infiltrate the acini and ductules and crowd beneath remaining epithelium, lifting it from its basement membrane. These cells engulf large numbers of yeasts and the histolytic effect of the organisms is no longer so obvious. *More chronically, there develops extensive inter- and intralobular fibrosis and a variable number of more typical granulomas.* The corresponding lymph node is greatly enlarged and the lesions in it parallel those in the udder (Fig. 4.169). The infection may metastasize to the lungs.

Mastitis caused by ***Mycobacterium*** spp. other than *M. bovis* also follows mammary infusion measures. These infections too cause very marked enlargement of the gland, but there is no systemic reaction, nodularity, or subcutaneous edema. *The basic tissue reaction is granulomatous and well restricted to lobules.* Giant cells are common, but the main infiltrating cells are histiocytes and lymphocytes organized in granulomatous formations that are often centered on oil droplets. Many of the lobules are completely destroyed by granulation tissue and there is considerable thickening and lymphocytic infiltration in the interlobular connective tissue. In the early stages, a ring of neutrophils may surround the oil droplets that contain large numbers of bacilli. Neither the organisms alone nor the oil alone is capable of provoking a granulomatous mastitis.

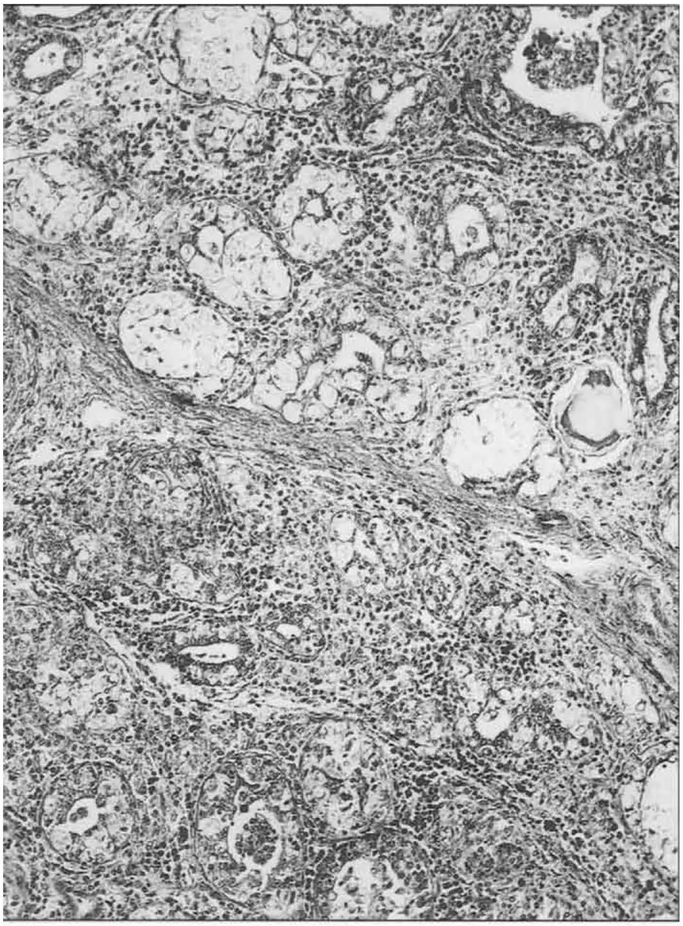

Figure 4.168 Chronic glandular atrophy with diffuse interstitial fibrosis in bovine **cryptococcal mastitis**.

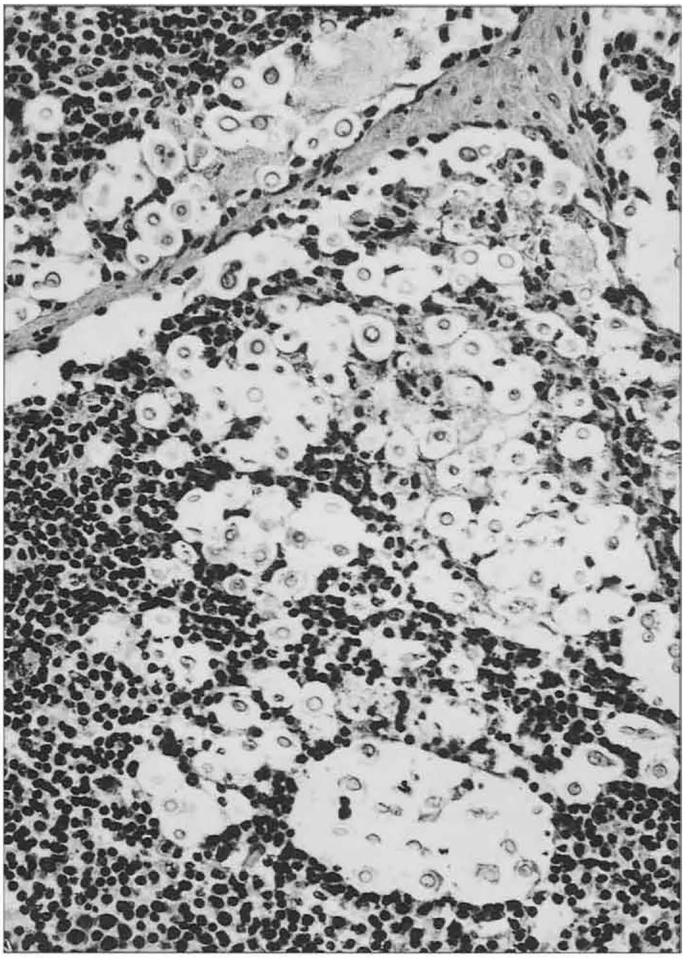

Figure 4.169 Supramammary lymph node from a cow with **cryptococcal mastitis**, showing characteristic "soap-bubble" appearance.

Candida spp. infection has usually occurred under the same conditions of infusion. Mastitis caused by ***Trichosporon*** species is also reported. The tissue changes were not examined in either of these infections, but the infection produced by *Candida* spp. is often acute and transient, the infecting organism disappearing in about 3 weeks. Candidiasis is more likely to occur in animals being fed brewers' grains.

Infection with ***Prototheca zopfii***, an achlorophyllous alga, can cause sporadic or epidemic mastitis that is refractory to treatment. Environmental wetness, muddiness, and the presence of organic material are conducive to the growth of *Prototheca* spp. Improper milking procedures and unsanitary infusion of intramammary antibiotics contribute to mammary gland infection. The mastitis caused may be mild clinical or chronic subclinical, and may cause a dramatic drop in milk production. Histological lesions consist of interstitial infiltrates of macrophages, plasma cells, and lymphocytes, with neutrophils in acinar lumens. The reaction becomes granulomatous with time. Algae are present in macrophages and free in the alveolar lumen and interstitium, and are more easily identified if stained with periodic acid–Schiff.

MASTITIS IN SHEEP AND GOATS

Mastitis in the ewe and goat is usually caused by *Staphylococcus aureus* or *Mannheimia haemolytica*. *Corynebacterium pseudotuberculosis* and *A. pyogenes* cause "cold" abscesses and probably gain entrance through skin wounds. Mastitis in the ewe and doe is important where milk is used for human consumption either directly or in products such as cheese, and because the mortality rate can be as high as 50%. Except for infection by *Mycoplasma agalactiae*, clinical mastitis usually affects only one gland. The range of organisms causing bacterial disease includes the species pathogenic in the cow.

S. aureus causes a galactogenic infection occurring very early in lactation, with a course and consequences paralleling the disease in the cow. The morbidity, however, is higher and may approach 25% of a flock. *Mannheimia haemolytica* causes mastitis in sheep on summer range at or near the end of lactation. It too is probably galactogenic and affects ~5% of a flock. There is an early acute phase with systemic reaction, but in the course of 48 hours the systemic reaction has subsided. The affected gland, usually one side, is greatly enlarged and tense, and the secretion becomes watery and contains flakes. Later there may be developing bluish discoloration and widespread necrosis of tissue. Animals that do not die develop abscesses in the course of a week or so with rupture and fistulation, and eventually most of the affected gland sloughs. Pneumonia in lambs has been reported to accompany this form of mastitis.

Contagious agalactia is primarily a disease of goats, sheep being slightly less susceptible, and is caused by *Mycoplasma agalactiae*. The disease is endemic in countries bordering on the Mediterranean sea. Diagnostic aids include improved serological testing and use of the polymerase chain reaction.

The name, contagious agalactia, merely emphasizes one, although perhaps the most consistent, feature of the disease, namely mastitis. *The disease is initially septicemic, and often fatal in this phase.* If the infected animal survives the acute stage, there may develop signs of localization in the eyes and periarticular tissues and, in the case of a lactating female, in the mammary gland. These are the sites in which localization is obvious, but it might be anticipated that *M. agalactiae* shares the affinity of this class of microorganisms for connective tissues and lymphatics and that it localizes in other less obvious places. The organisms are eliminated in the secretions and discharges. Infection is probably by ingestion, but it can be galactogenic and per conjunctivam.

Lactating females and kids are particularly susceptible to the infection and likely to succumb in the septicemic phase of the disease. Pregnant females may abort or deliver live but infected fetuses. There are no specific lesions in the septicemic phase, but the organism can be cultured from all tissues and from the blood. In infections of lesser severity or following recovery from the peracute disease, the febrile reaction subsides, and lameness, keratoconjunctivitis, and alterations of the mammary secretion occur. This complete triad is not always present, and even when there are signs of localization, the animal may continue to decline and die in 2 weeks or so.

The mastitis apparently is an inflammation primarily of the interstitial tissue with secondary changes in the acini. Mild inflammations, although they cause cessation of lactation, may be followed by full functional recovery, but the more severe reactions may lead to progressive fibrosis with parenchymal atrophy. The organisms are eliminated in the milk and in other discharges for many months in animals that survive the initial stages of the disease. Lameness is indicative of *arthritis and periarthritis* and this is more common at the carpal and tarsal joints than at others. Inflammatory edema thickens the periarticular tissues. The synovial membranes may be normal or they may be hyperemic or ulcerated with an increased volume of turbid fluid that may be blood-stained. The ocular lesions, which are present in ~50% of cases, consist of mucopurulent conjunctivitis and keratitis that may be complicated by ulceration and staphyloma.

Mastitis affecting both glands of ewes is a common manifestation of infection by the lentivirus of **maedi-visna** (ovine progressive pneumonia; see Vol. 2, Respiratory system). The mammary disease can be of much earlier onset and of much higher incidence than neurologic or pulmonary disease, although the expression of the various syndromes may be strongly influenced by breed and genotype of the hosts. The presenting indications of lentivirus mastitis are reduced milk yield, poor preweaning growth of lambs, and progressive atrophy and induration of both glands. The virus is present in the mammary gland shortly after exposure. The severity of the lesions increases with the duration of infection. The virus replicates in circulating monocytes and more freely in tissue macrophages. The presence of macrophages in the mammary interstitium encourages a local inflammatory response consisting largely of lymphocytes and plasma cells. *The lymphocytic-plasmacytic infiltrations are diffuse in the interstitial and periductal connective tissue and lymphatic nodules are formed.* Fibrosis is not a feature of the response. Degeneration and loss of acinar and ductular epithelium that is present in advanced lesions may be a consequence of the infiltration and not a direct virus effect.

The lentivirus of **caprine arthritis-encephalitis** is closely related to that of maedi-visna, and the pathogeneses of the infections in the separate species have very much in common. Mastitis does occur in the caprine disease and has similar morphological features to that in the ewe but is not a prominent component of the syndrome.

The toxic principle of the **avocado**, *Persea americana*, is *persin*; only some varieties of the plant are toxic. Mammary injury is reported in lactating goats. The gland becomes swollen, firm, and congested, especially in dorsal parts, and there may be subcutaneous edema affecting the gland and adjacent body wall. Histologically, there is *widespread degeneration and necrosis of secretory epithelium*, more severe at the centers of the lobules, and patchy loss of duct epithelium. Cellular inflammatory response is minimal. Restitution of function may be incomplete.

MASTITIS IN DOGS AND CATS

In the dog and cat, inflammations of the breast are uncommon and nonspecific. The most important is *nonspecific acute mastitis*, which is usually confined to early lactating or pseudopregnant periods. The exciting agents are staphylococci and streptococci, the former being the more common, and both are believed to gain entrance via fissures in the nipples and adjacent skin and to spread by way of both the ducts and the lymphatics. The staphylococci may cause gangrene, but they tend to localize in the course of a few days and form abscesses, while the streptococci tend to produce a more diffuse and spreading purulent inflammation. The acutely affected glands are large, firm, and edematous, and the overlying skin becomes taut and shiny. Only a small amount of gray secretion can be expressed; it may be blood-tinged or contain pus. The *chronic cases of mastitis* in these species cannot be satisfactorily distinguished from neoplasms until examined cytologically. Indeed, mastitis is often superimposed on cystic mammary hyperplasia and on mammary neoplasia, especially those tumors that involve the ducts.

MASTITIS IN SWINE

Chronic granulomatous mastitis, affecting one or more glands, is occasionally observed in old sows. The lesions are of *botryomycotic* type, being suppurative granulomas, and most of them are produced by *Staphylococcus aureus*. *Actinomyces bovis* was an important cause of this form of mastitis some decades ago, but presently appears to be of very low incidence. It is true for sows as for cows that the designation "actinomycosis of the udder" refers more usually to staphylococci than to actinomycotic infection. In either event, it appears that the infections are percutaneous, entry being gained through wounds of the skin.

Mastitis caused by coliform bacteria occurs as a very acute infection shortly after parturition. It usually affects more than one gland and produces lesions that are similar to those of cows with coliform mastitis. Hemorrhagic mastitis is very rare in sows, and the usual gross appearance is of slight to moderate reddening of the glands with severe edema. Affected mammae are firmer than normal. The severe systemic reaction and the occasional presence of clinical synovitis indicate that septicemia may occur. The pathogenesis is unknown, but ascending infections from environmental contamination may be important.

The important syndrome in sows is known as the **mastitis–metritis–agalactia syndrome**. It occurs in sows 12–48 hours after parturition and is seen as lethargy, fever, swelling, and firmness of the mammary glands, and agalactia. There is some overlying hyperemia, and edema may be extensive. *There are probably several causes for the presence of agalactia in postpartum sows*, and acute infectious mastitis such as that due to coliforms is one. The mastitis–metritis–agalactia syndrome is most common in intensive units, and hormonal dysfunction stimulated by sudden changes in management may be precipitating. Metritis is seldom a significant part of the syndrome.

GENERAL CONSIDERATIONS

Mastering pathology of the male reproductive system is more than knowing how to recognize the diseases that affect each part of the tract. Understanding mechanisms and identifying clinical significance are very important. Arriving at an accurate diagnosis is facilitated by similarities among the various species, such that familiarity with a disease in one species generally permits the pathologist to make the same diagnosis in another species. There is a short list of common diseases, which we will identify, for each of the anatomical locations in the male reproductive tract.

Understanding the basic mechanisms of disease, especially in companion animals, is much more problematic since there has been little interest in or funding for detailed research. Prospective studies are very difficult to manage for the same reasons. Diseases of production animals frequently are handled pragmatically, i.e., cull the affected animal. Hence, there are few studies of the mechanisms of disease of the male genital tract in domestic animals. Information gleaned from a variety of human, laboratory animal, and/or toxicological studies has been used to draw possible parallels with diseases in domesticated species.

The testes are often considered the center of the "male reproductive universe," but not every disease of the scrotal contents involves the testes. "Orchitis" is a common clinical diagnosis even though the inflammation and/or infection usually involve the tunica vaginalis, epididymis, or spermatic cord. The testes only infrequently are involved directly in inflammatory reactions. Similarly, the ability of spermatozoa to stimulate a florid inflammatory reaction is overlooked, and bacterial involvement and abscesses are high on the list when inflammatory conditions are suspected. *We will highlight common misconceptions in the diagnosis of male reproductive disease.*

From a functional and pathogenetic point of view, the male reproductive system, focused on successful delivery of viable spermatozoa to the female, is composed of a *production unit* (the testis), a *maturation* *and maintenance unit* (epididymis), and a *transportation unit* (various parts of the ducts and accessory genital glands). Each will be dealt with in turn. The male still comprises 50% of the reproductive unit.

Spermatogenesis

Successful spermatogenesis is a complex process that now is being unraveled, because of interest in the effects of toxicants and drugs on fertility. Early studies examined the effects of temperature on spermatogenesis, and individual instances of failure were investigated morphologically. However, now we have the ability to investigate the role of gene expression, cellular interactions, accelerated apoptosis, various cytokines, and hormonal interactions on the function of the germinal compartment.

Spermatogenesis requires a complex interaction among germ cells, Sertoli cells, and interstitial endocrine (Leydig) cells.

Sertoli cells are very complex in their structure and function. The majority of Sertoli cells are present at birth or soon after. They extend from the basement membrane to the luminal surface, and have a large surface area. Attachment to adjacent Sertoli cells and to germinal cells is by a variety of junctional complexes, and this forms the blood–testis barrier. Sertoli cells function to maintain the integrity of the seminiferous epithelium, compartmentalize the seminiferous epithelium into basal and luminal compartments, secrete fluid, form the tubular lumen, phagocytose degenerating and necrotic cells, deliver nutrients to germ cells, metabolize steroids, translocate germinal cells, secrete proteins, regulate the spermatogenic cycle, and mediate hormonal effects on the germ cells. These many functions are potential targets for abnormalities.

Spermatogenesis begins with stem cells that proliferate by mitosis, undergo a meiotic phase, and finally differentiate. These stages correspond to *spermatogonia, spermatocytes, and spermatids*, respectively. The spermatogonia are subdivided into proliferative and differentiating types of stem cell. They divide by mitosis to produce most of the cells that go on to form spermatozoa. Meiotic division has a prolonged prophase, but subsequent phases proceed rapidly. The spermatids are formed as a final, differentiating step. *Spermiation* is the active release of spermatozoa by Sertoli cells to the lumen, for subsequent transport through the duct system.

Spermatogonia are exposed to interstitial tissue fluids. Occluding junctions of Sertoli cells mostly form the blood–testis barrier. Spermatocytes and spermatids within the tubule are "external" to the blood–testis barrier. Apoptosis of germ cells at each stage of development occurs as a natural phenomenon (see below), and Sertoli cells phagocytoze degenerative and necrotic cells.

Control of spermatogenesis involves a complex interaction of central and local factors. Luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are the major pituitary hormones regulating spermatogenesis. Interstitial endocrine cells have LH receptors that, when coupled with LH, induce testosterone production. Testosterone is essential for spermatogenesis; Sertoli cells, and perhaps germinal cells, have testosterone receptors. Testosterone is known to inhibit apoptosis of germ cells. FSH directly stimulates the Sertoli cells and perhaps the germinal cells. FSH and testosterone probably act synergistically.

Local control of spermatogenesis is also highly dependent on local autocrine and paracrine factors; the number of factors recognized is increasing exponentially. Sertoli cells produce inhibin, which inhibits FSH production. Germinal cells, Sertoli cells, peritubular cells, and interstitial endocrine cells secrete many cytokines/growth factors. These cells are influenced, in turn, by a large number of similar signaling molecules. Germ cells express Fas (APO-1, CD95), a transmembrane receptor molecule that transmits an apoptotic signal in the cell when it is bound by a Fas ligand. Sertoli cells express Fas ligand, and regulators of apoptosis are found in the testis, including the Bcl-2 family of proteins and the p53 protein. Apoptosis is a normal phenomenon regulating cell populations, but induction of apoptosis or increased apoptosis also occur with exposure to toxic compounds, depletion of growth factors, alteration of hormonal support, exposure to heat, radiation, transient ischemia, or treatment with chemotherapeutics. Testes with impaired spermatogenesis, such as hypospermatogenesis or maturation arrest, may have increased apoptosis.

There are well-recognized changes in spermatogenesis with **age**. The size of the testis decreases progressively from puberty into adult life. Initially, the seminiferous tubules increase in length and diameter, and the testicular volume increases. However, from early adulthood onward, there is a gradual reduction in tubular diameter. The absolute number of Sertoli cells probably declines from puberty on. A decline in the number of spermatocytes and an increase in apoptosis both contribute to reduced testicular mass to various degrees in different species. A concurrent increase in the mass of the testicular interstitial tissue typically occurs with age, and the basal lamina of the seminiferous tubule increases in thickness.

Immunity to spermatozoa

Any condition that causes leakage of spermatozoa or spermatozoal antigens into the extratubular compartment is potentially complicated by inflammatory and immunologic responses. The response to spermatozoa is variable, but innate or nonspecific immunity and humoral and cellular mechanisms are involved. Spermatozoa have a cell wall of lipids and phospholipids; they incite a foreign body-type reaction, and the large amount and keratinoid composition means that degradation is slow. In addition, immune responses are florid and result in the accumulation of many immunoglobulin-producing cells as well as CD4 and CD8 lymphocytes. Up-regulation of major histocompatibility complex (MHC) I in epithelial cells also occurs. The reaction leads to chronic inflammation and fibrosis, and continued obstruction and disruption of tubules. Spermiostasis, spermatocele, and/or further sperm granulomas are the consequence.

Antispermatozoal antibodies are found in serum, genital secretions, or both. The presence of these immunoglobulins in plasma is associated with infertility in several species including humans. There is a lack of information on their presence in genital fluids, where they have the greatest impact. Spermatozoal antigens gain entry to the interstitium due to trauma or rupture of a duct or tubule following inflammation or obstruction. Specific conditions that result in sperm granulomas include blind-ended efferent ductules (sperm granuloma of the epididymal head or efferent ductules), segmental aplasia of the mesonephric ducts, adenomyosis, and epididymitis. Infection of dogs with *Brucella canis* can cause the formation of antispermatozoal antibody, and it is anticipated to occur in vasectomy and other causes of obstruction of ducts.

Serum immunoglobulin may gain access to the spermatozoa through any part of the reproductive tract, but the efferent ductules are probably the most accessible site, because the barrier between the internal and external compartments is less tight. Local immunoglobulin production can occur at any location in the tract, but the accessory genital glands are the most common site (see below).

Immunity in the reproductive tract

Innate, humoral, and cellular immunity are all expressed in the male genital tract. The innate mechanisms are, arguably, the most important. The male genital tract has little ability to compensate for direct injury. The testes are bounded by the tough and relatively inelastic tunica albuginea, and any sudden increase in internal pressure or swelling, be it caused by hemorrhage or edema, results in testicular necrosis. The epididymis and deferent duct (ductus deferens) form a single small-diameter tube that is easily obstructed and damaged, and it is free from the usual systemic immune surveillance. There is always the specter of inflammation and acquired immunity to spermatozoal or secretory products.

Normally very little immunoglobulin enters the seminal fluids, and with a few exceptions, lymphocytes are not found in the interstitium of reproductive structures in normal male animals, although they are occasionally seen in the interstitium of the epididymis of the dog. Their presence in the interstitium of the testis, epididymis, and deferent duct is presumed to be acquired. Macrophages are present in the normal interstitial tissues of all species. Epithelium can express MHC II molecules if inflammation is present. The various ducts of the male reproductive tract contain intraepithelial leukocytes, especially CD8 lymphocytes. The accessory genital glands are believed to be the main location for plasma cells, which presumably add immunoglobulins to the seminal fluid to help prevent access of ascending agents to the deferent duct and epididymis. Local humoral immunity develops in the accessory genital glands, and is predominantly IgA-based in those species that have been examined.

One of the unfortunate side effects of having spermatozoa not recognized as "self" is the necessity of maintaining these cells completely separate from immune surveillance. This provides microbial organisms a location within the lumen of ducts and tubules where they can grow and cause damage. Once the body recognizes the injury and recruits inflammatory cells, there often is too much damage to permit repair or regeneration. In addition, the very processes of inflammation, including the release of free radicals by leukocytes, damage the tract further. As in many other sensitive tissues, *the damage done by inflammation may be a major cause of dysfunction.*

Anomalies of development

Production of a normal ejaculate depends on a combination of factors. These include normal development of the reproductive tract, and normal spermatogenesis, spermatozoa maturation and transport, normal accessory genital gland function, and nervous, musculoskeletal, and psychological factors. While the exact mechanism of development of the male genital tract has not been determined, research in several species, especially rodents, suggests the following.

Reproductive differentiation requires appropriate sequential development and regression of the gonadal mesenchyme, paramesonephric (Müllerian) and mesonephric (Wolffian) tubules and ducts, and the tissues of the gonadal ridge. When all steps occur normally, genotypic, gonadal, and phenotypic sex is matched. Male domesticated mammals normally have an XY genotype, although XX males can occur if a sex-determining factor is present. In XY males, this is the *testis-determining factor* (TDF), the production of which is governed by the sex-determining region (SRY) of the Y chromosome.

During early embryonic development, germ cells migrate from the yolk sac to the genital ridge. The constituents of the primitive gonad are the germ cells, mesenchymal cells, coelomic epithelial cells, and mesonephric epithelial cells. These form the four major cell types in the gonad – the germ cells, supporting cells, steroid-producing

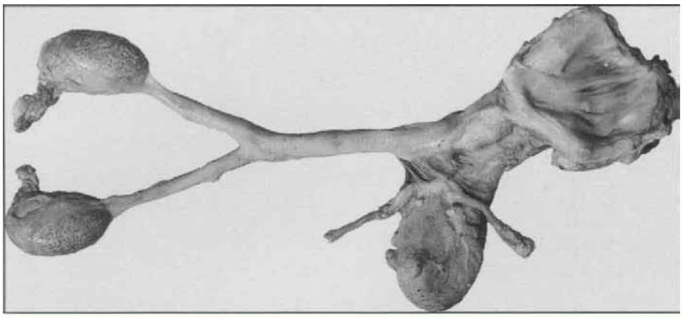

Figure 5.1 **A male pseudohermaphrodite bovid** with tubular genitalia that is predominantly female, but both gonads are testes.

cells, and unspecialized mesenchyme. The TDF causes the germ cells to go into mitotic arrest, the supporting cells become the Sertoli cells, the steroid-producing cells become the interstitial endocrine cells (of Leydig), and the mesenchyme develops the testicular pattern. The ducts are derived from the mesonephric ducts. The genital sinus and external genital tubercle are bipotent. Male differentiation occurs before female differentiation and is dependent on the production of hormones such as testosterone.

The male phenotype depends on the production by the Sertoli cells of *Müllerian duct inhibitory substance* (MIS), which causes the paramesonephric (Müllerian) duct to regress. Interstitial endocrine cells produce testosterone that inhibits further female differentiation, prevents the mesonephric ducts from regressing, and induces development of the penis and scrotum. The mesonephric ducts give rise to the epididymides, deferent ducts, and vesicular glands.

Developmental abnormalities of the male genital system include XXY (Klinefelter's syndrome), XX sex reversal, persistent Müllerian syndrome, translocations, and androgen insensitivity (testicular feminization). These are manifested clinically as *ambiguity in phenotype* and/or *infertility*.

- Cats, bulls, dogs, pigs, horses, and sheep that have an **XXY genotype** or a mosaicism with XXY chromosomes may have hypoplastic internal genitalia. The most well known of these are male *tortoiseshell or calico cats*, which are almost always infertile, and have testicular hypoplasia.
- **XX sex reversal** occurs in goats, dogs, and pigs. In goats this is called the *polled/intersex syndrome* (PIS) because it is common in polled animals, where polled XX homozygotes are hermaphrodites. They range from sterile males to females with testes. In dogs, affected American Cocker Spaniels can vary from XX males to XX true hermaphrodites. In pigs, it is a common anomaly that may be confused with freemartinism.
- Animals with **androgen insensitivity (testicular feminization)** are male pseudohermaphrodites – they have testes, no tubular genitalia, but are phenotypically female (Fig. 5.1). Cats, horses, and cattle are reported with this condition.
- Animals with the **persistent Müllerian duct syndrome** are phenotypically male and may be fertile. Affected Miniature Schnauzer dogs may develop hydrometra and pyometra of the remnants. Many are also cryptorchids. The defect appears to be insensitive to MIS rather than a lack of production of MIS.

Gynecomastia is occasionally seen as a solitary lesion in males. There are reports of bucks from high milk production lines that develop mammary glands.

SCROTUM

The scrotum is an outpouching of perineal skin and is lined by evaginations of the peritoneum. The theory that the development of the scrotum is directed solely to providing a superficial cool environment for the testis is too limited. The storage receptacles for mature spermatozoa in most mammals also need to be located in sites in which the temperature is less than core temperature. Furthermore, since maturation of spermatozoa is a slow process, a fact reflected in the extraordinary length of the epididymal tubule, the scrotum may have evolved to accommodate the epididymis. Finally, the testicular artery, which is quite separate from the blood supply to the epididymis, has, by virtue of its length, physiological consequences that are assisted by the development of an abdominal evagination.

The structure of the scrotum is adapted to its function of maintaining the testis at a temperature less than core. The scrotal skin is thinner than skin elsewhere and is well covered with hair only in the cat, although in all species it is well supplied with apocrine sweat glands; there is little or no subcutaneous fat or connective tissue. The contractility of the scrotum is a property of the *dermal dartos* that consists of fibroelastic tissue and smooth muscle. Thermoregulatory function is shared by the *cremaster muscle*, which regulates the proximity of the testis to the abdominal wall, and the *pampiniform plexus* of veins, which ensures maximum contact of cooled venous circulation with the warmer arterial blood. If the testes of the common domestic animals are maintained at or above normal body temperature, degeneration or arrest of development of the seminiferous epithelium occurs, although impairment of the interstitial endocrine cells is minimal or absent. Experimental "shortening" of the scrotum of ram lambs results ultimately in mature rams that have small testes and epididymides, low spermatozoa production, and in most cases no epididymal spermatozoa reserves.

The formation of the scrotum from the paired genital swellings of the embryo, and its full development at puberty, requires gonadotrophin-induced androgens, and is dependent therefore on the development of testes. **Anomalies of scrotal development** are simple in their expression in spite of the complicated steps in the development of the paired primordia. *Apparent absence of the scrotum* has been observed in cryptorchidism. Various degrees of *bifurcation of the scrotum*, and *scrotal clefts*, represent failures of fusion

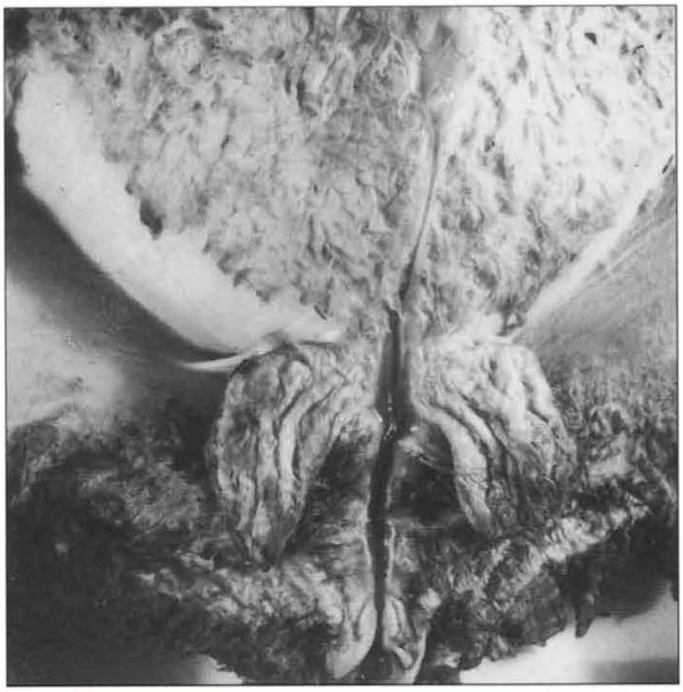

Figure 5.2 A ram lamb with complete **hypospadias**, including bifurcation of the scrotum.

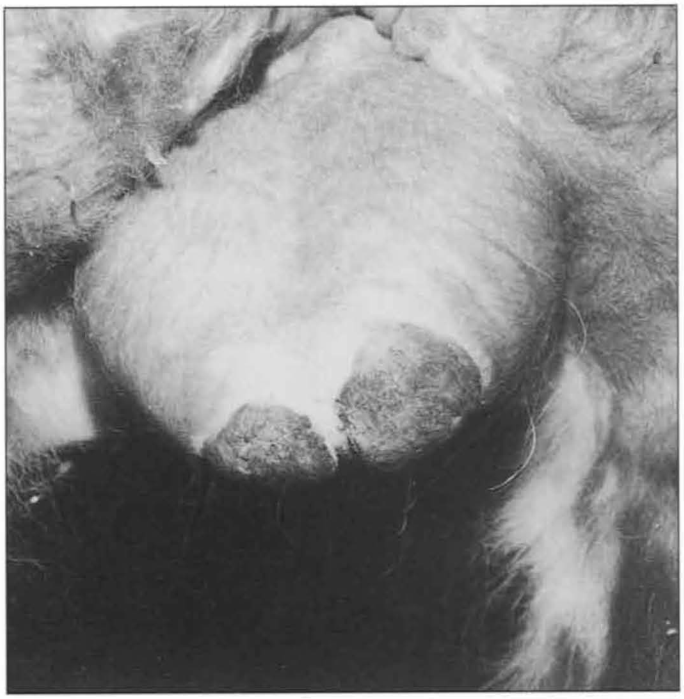

Figure 5.3 **Scrotal frostbite** in a bull. (Courtesy of WF Cates.)

(Fig. 5.2). Such defects may be local and accompanied by hypospadias and other defects such as atresia ani, or reflect gonadal dysgenesis in intersex states.

Range bulls exposed to extreme cold may develop **scrotal frostbite**. A higher incidence of lesions in old bulls is attributed to their more pendulous scrotums. Lesions consist essentially of necrosis of skin on the ventral aspect of the scrotum and vary from mild (about 3 cm diameter) to severe, in which more than 75% of the scrotum is affected (Fig. 5.3). Associated changes include scrotal swelling, tunic adhesions, and decreased semen quality.

Enlargement of the scrotum is mostly due to edema, which has local or systemic causation (see under Tunica vaginalis). Skin changes resulting from a dietary deficiency of zinc may involve the scrotum. In dogs, white-yellow crusts may occur, and parakeratosis is seen histologically. In sheep, there is cessation of wool growth on the scrotum. Pemphigus erythematosus and drug eruption, such as in dogs in response to the antifungal flucytosine, may also be manifested by changes in scrotal skin.

Because of its delicacy, scrotal skin is especially vulnerable to inflammation. The expressions of inflammation are influenced by the abundant arteriovenous anastomoses that are present, and the effects include impairment of the function of the tunica dartos. **Scrotal dermatitis** frequently is caused by nonspecific environmental irritants. Important specific causes in ruminants include *Dermatophilus congolensis*, *Besnoitia besnoiti*, fungi, and various ectoparasites, especially *Chorioptes bovis*. Poxvirus infection of the scrotum of bulls may occur as diffuse or focal lesions. In dogs, the scrotum may also be a preferred site for localization of *Prototheca wickerhamii*, causing diffuse pyogranulomatous dermatitis with ulceration. These infections are discussed in Vol. 1, Skin and appendages.

Although the scrotal skin of bulls seems especially susceptible to infection by *Dermatophilus congolensis*, possibly because of the role of ticks in transmission, testicular degeneration does not necessarily ensue. However, severe, prolonged infection may result in thickening of the skin to 1 cm, with advanced testicular degeneration and sterility. Infection of scrotal skin of bulls and goats by *Besnoitia besnoiti* also may lead to severe testicular degeneration. This infection is not limited to skin, and the small nodules containing white gritty material may be observed grossly in the subcutis of the scrotum as well as in the tunics, the parenchyma of the testis, and in the epididymis. Vascular damage is considered important in the development of lesions, and large numbers of *Besnoitia* cysts may be present in the intima of vessels in the pampiniform plexus. A feature of the testicular lesions is extensive intratubular mineralization.

Infestation by *Chorioptes bovis* is common on the scrotum of rams. Indeed, the scrotum appears to be a preferred site for the mite. The lesions can be mild but are frequently sufficiently severe to influence the size and function of the testis. In such cases there is marked thickening of skin and matting of overlying hair and wool by secretions and exudate. *Linognathus pedalis*, the foot louse of sheep, and *Haematopinus eurysternus* in cattle also can be important causes of scrotal dermatitis. Sarcoptic mange, with typical crusted lesions, may especially involve the scrotum in goats and cats.

The flea *Tunga penetrans* also may cause scrotal dermatitis in the boar by burrowing into the skin. Scrotal myiasis in most species is caused occasionally by screwworm, including both *Chrysomya bezziana* and *Cochliomyia hominivorax*, and other fly larvae. Prior ulceration or laceration predisposes to myiasis.

Any of the **neoplastic diseases** of the skin may occasionally arise on the scrotum. *Melanotic tumors* and *mast-cell tumors* are not uncommon in the scrotal skin of the dog. Varicose tumors of blood vessels in the scrotal skin, referred to as **hemangiomas**, occur in dogs and boars. In dogs, the lesions commence as focal pigmented areas and progress to a small plaque and then to capillary, then cavernous, hemangioma. Microscopically, small arterioles are seen between cavernous spaces that may extend quite deeply into underlying tissue.

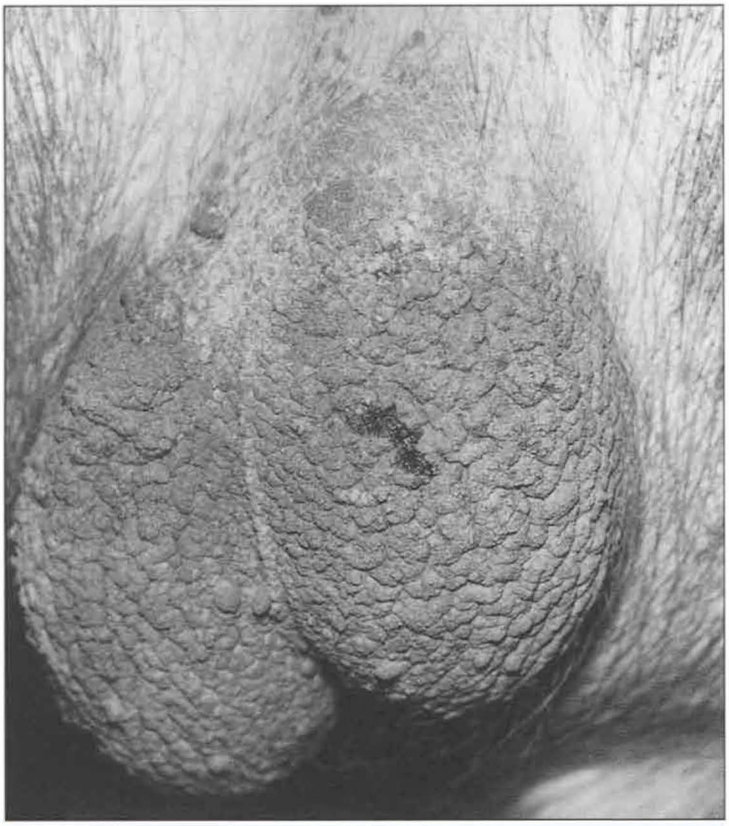

Figure 5.4 Multiple **scrotal hemangiomas** in a boar.

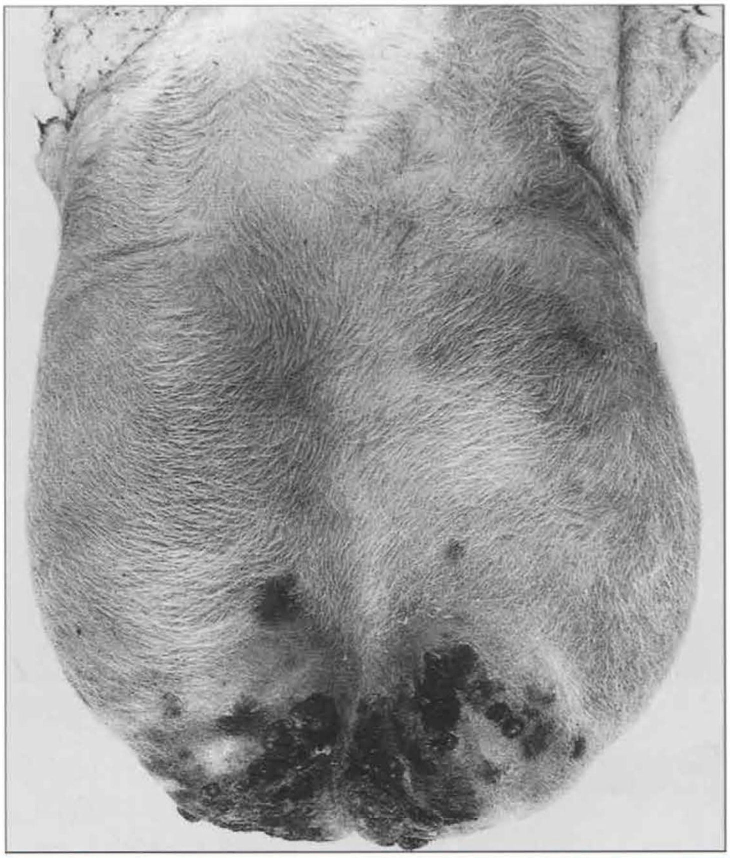

Figure 5.5 **Varicose dilation** of scrotal veins in a bull.

The lesions may become ulcerated and severe hemorrhage may occur. In boars, the multiple "warty" lesions are unsightly and may occasionally bleed, but do not appear to affect fertility (Fig. 5.4). Such lesions are benign and, as in dogs, they may not be true neoplasms. Age, altered hemodynamic forces in the capillary bed of the scrotal dermis, and genetic predisposition are factors that might be involved in the development of these abnormalities.

Varicose dilations of scrotal veins occur in older bulls. They appear as flattened and irregular thickenings of the scrotal skin. The overlying epithelium usually is normal unless it ulcerates, when oozing of blood occurs (Fig. 5.5). The affected venous channels are irregular in shape, widely dilated, and have thickened walls. Thrombosis occurs when the lesion is traumatized.

TUNICA VAGINALIS

The tunica vaginalis is an extremely thin mesothelial layer continuous with and structurally similar to the peritoneum. The scrotum and testis, which are covered by the parietal and visceral layers, are separated by the cavity of the tunica vaginalis, and must be considered in any condition involving the latter.

The cavity of the tunica vaginalis communicates with the peritoneal cavity and is susceptible to the accumulation of fluid, **hydrocele**, in conditions leading to ascites, anasarca, or local lymphedema. Hydrocele may lead to quite severe testicular degeneration on the involved side and to lesser damage on the opposite side, mostly in response to impaired thermoregulation. Scrotal hydrocele, with diminished sperm quality, has been identified as a herd problem in bulls. Clinically, the fluctuant nature of the enlarged scrotum, with a scrotal circumference up to 60 cm, is indicative of edema, and if affected bulls are examined at necropsy there is obvious ascites. If hydrocele persists, the tunics become increasingly fibrotic. Ostertagiasis and eperythrozoonosis have been incriminated as causes of such hydrocele.

Lymphatic drainage from the cavity of the tunica vaginalis is through scrotal lymphatics beneath the parietal tunic, and this

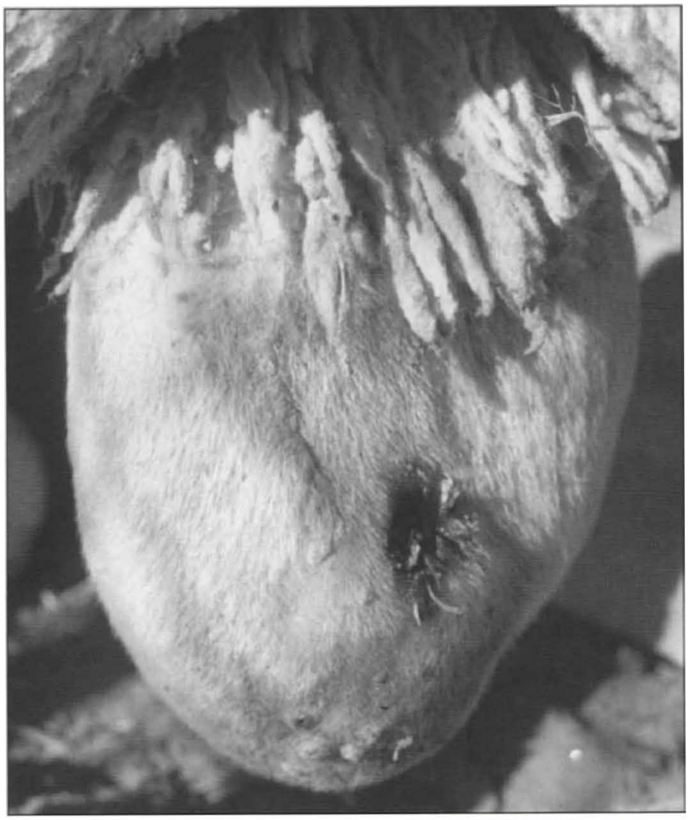

Figure 5.6 Fistulous tract through the scrotum of a ram with severe epididymitis and periorchitis.

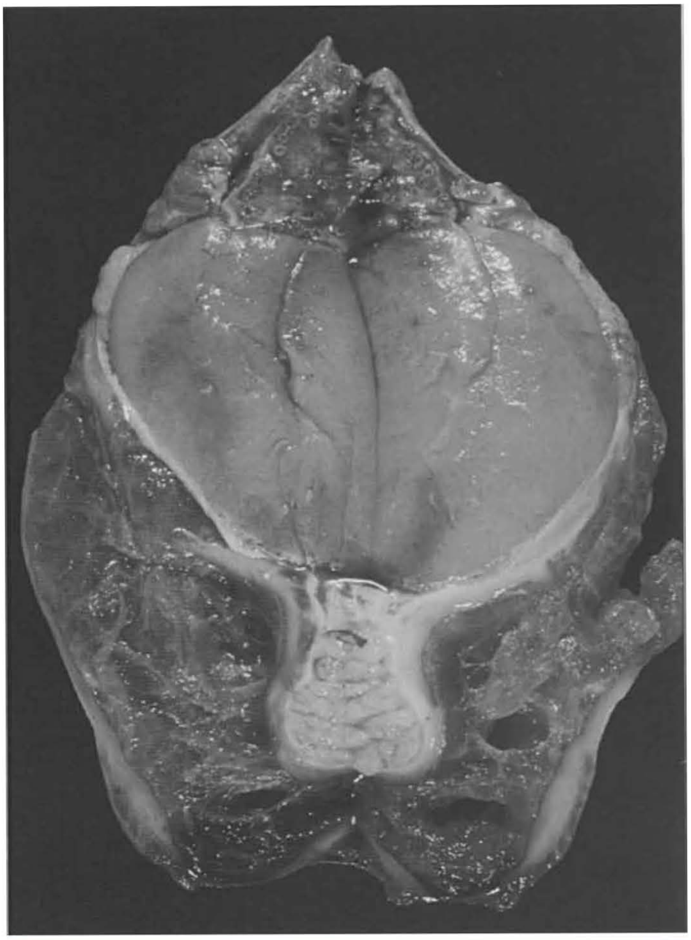

Figure 5.7 Periorchitis secondary to epididymitis in a ram. Fibrin and edema fluid are present within the cavity of the tunica vaginalis.

accounts for the spread of inflammatory processes from the cavity of the tunica to the scrotum. In the stallion, scrotal swelling, with edema of the prepuce, is seen in many conditions, including peritonitis, equine viral arteritis and other vasculitides including purpura hemorrhagica, and surra, caused by *Trypanosoma evansi* infection.

Hematocele, the accumulation of much blood in the vaginal cavity, is mostly the result of trauma. It is not uncommon in boars housed together.

The visceral tunic is an integral part of the testicular capsule, the other two layers being the *tunica albuginea* and *tunica vasculosa*. The tunica albuginea is composed of inelastic collagen and fibrous tissue, and smooth muscle through which the tunica vasculosa is normally visible. In spite of the presence of smooth muscle, the capsule is not significantly contractile; it probably contributes to the flow of semen by maintaining intratesticular pressure. The tunic is thickened and opaque in testicular hypoplasia and atrophy.

Inflammatory changes in the tunica vaginalis may be part of disseminated infection, with lesions typical of the infection, such as feline infectious peritonitis, tuberculosis, caseous lymphadenitis, and the various diseases causing polyserositis in pigs. Suppurative inflammation also occurs as an extension of scrotal injury or from epididymitis (Fig. 5.6).

Severe periorchitis is a complication of epididymitis irrespective of cause, but is particularly found in animals with *Trypanosoma brucei* infection, and in rams infected with *Brucella ovis* or *Actinobacillus seminis* (Fig. 5.7). Ectopic parasites, such as equine strongyles, can be found on the tunics. *Setaria labiatopapillosa* causes granulomatous periorchitis in bulls, and lesions occur particularly after worms are killed by anthelmintic treatment. A high occurrence of eosinophilic, then granulomatous, periorchitis in buffaloes is also attributed to *Setaria* sp. Cysts of taenid larvae, mostly *Cysticercus tenuicollis*, may be found in the scrotal cavity of rams, unassociated with inflammation. In dogs, rare peritoneal cestodiasis caused by larvae of *Mesocestoides* sp. may involve the vaginal tunics, with saccular dilatations within the tunics, thickening of the spermatic cord, and pyogranulomatous inflammation involving the tunica albuginea and extending into the testes.

Adhesions between the visceral and parietal layers of the tunica vaginalis are common, especially in older animals. Adhesions are at first fibrinous, reflecting acute periorchitis, but later become fibrous. Fine, threadlike, fibrous adhesions located at the epididymal tail in bulls are normal. Although adhesions may result from infectious periorchitis and may be associated with epididymitis, it seems probable that most are the result of trauma. Most adhesions are focal and solitary and are not accompanied by lesions in the testis or epididymis; they probably are of little consequence.

Cystic lesions of the tunica vaginalis may be loculations within adhesions. Very small cysts, probably of paramesonephric duct origin, are common adjacent to the head of the epididymis in the horse, and are referred to as "appendix testis" or Morgagni's hydatid.

Neoplastic disease *involving the tunica vaginalis is rare*, even as secondary extension from the testis or scrotum. *Mesotheliomas* with primary involvement of the tunica vaginalis occur in the dog and

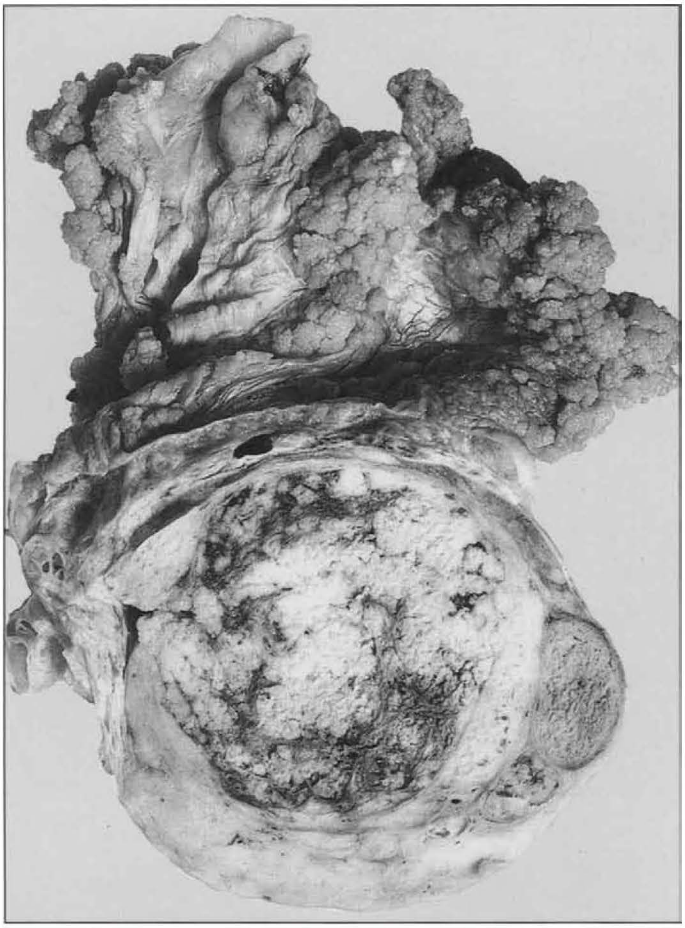

Figure 5.8 Papillary mesothelioma of the tunica vaginalis that covers the scrotal contents of a dog.

bull (Fig. 5.8). Extension of the tumor into the peritoneal cavity has been observed in the dog. Ultrastructural or immunohistologic study may be necessary to differentiate such mesotheliomas from adenocarcinoma. Origin of intrascrotal mesothelioma from the paramesonephric duct remnant has been suggested. There is a report of a lipoma occupying the right scrotal cavity in a ram, causing compression of, but apparently not directly involving, the testis.

TESTIS AND EPIDIDYMIS

Spermatozoa develop in the *seminiferous tubules* and pass through the *straight tubules* into the *intratesticular rete* within the mediastinum testis. They then leave the testis via the *rete testis* and enter the *efferent ductules*. The efferent ductules number between 13 and 20, depending on the species. Most join the single duct of the *epididymis*, but it is common in most species for one or more to end blindly. The epididymis is long and tortuous, and divided into many distinct areas. For this discussion, three main areas will be referred to: the *head, body, and tail*. The tail terminates in the *deferent duct*. Disease of one area has effects on other regions, and some diseases affect all areas.

Pathologists often examine individual testes or small biopsies rather than whole groups of animals. Gross and histological assessment of reproductive tissues is a valuable tool if used appropriately. Assessment of a problem often requires collaboration of the cytogeneticist, endocrinologist, theriogenologist and pathologist, who, alone, may not be able to determine the complete pathogenesis. For the pathologist to function optimally, appropriate samples must be collected and processed. For many of the diseases and the tissues, routine fixation with 10% formalin is adequate, but for a detailed assessment of spermatogenesis, or the histological appearance of seminiferous tubules, rapid fixation after death or collection (within minutes in many species) in Bouin's fluid or Zenker's fluid, with paraffin embedding, is necessary. Plastic embedding is the method of choice for a detailed assessment of the spermatogenic cycle. Inadequate fixation or suboptimal processing of testicular tissues will cause artifacts that cannot be distinguished from degeneration.

Normal spermatogenesis requires a normal scrotal testis in domestic mammals. The testis varies in its gross and microscopic appearance among the species, mostly in the extent to which the testis is divided into regions by fibrous tissue septa. This division is marked in the stallion, less so in the dog and boar, and mostly absent in ruminants. The basic microscopic appearance is similar – the testis is divided into the *interstitial or intertubular compartment* and the *seminiferous tubular compartment*. The interstitial endocrine cells are the major resident of the intertubular compartment; macrophages are another important cell type.

The interstitial compartment is a unique immunological environment. Nonspecific immunity is normal, but humoral and cell-mediated immunity is altered such that allogeneic and xenogeneic tissue transplants are maintained for a prolonged period. This state is dependent on the presence of testosterone, and is related in part to Fas ligand expression by Sertoli cells that induces apoptosis of Fas-expressing T cells. This environment is thought to provide protection to the germinal cells, and prevent autoimmune reactions or recognition of germinal cells by the immune system.

The peritubular cells and the basement membrane of the seminiferous tubule delineate the tubular compartment. Sertoli cells and germinal cells make up the intratubular compartment. The normal tubular diameter is 146 μm in the stallion, 180 μm in the dog, and 236 μm in the boar.

The normal testis is pale pink or even almost white. This is presumably because of the large quantity of chromatin material. Abnormalities that result in a lowering of spermatogenesis result in the dominance of other pigments – especially lipochrome pigments. The testes of boars become progressively brown with age, and are brown if degenerate.

A frequent misdiagnosis is made in equine fetal and neonatal gonads. Fetal testes undergo hypertrophy because of hyperplasia of the interstitial endocrine cells. These cells contain lipochrome pigments that are especially noticeable during the atrophic stage that

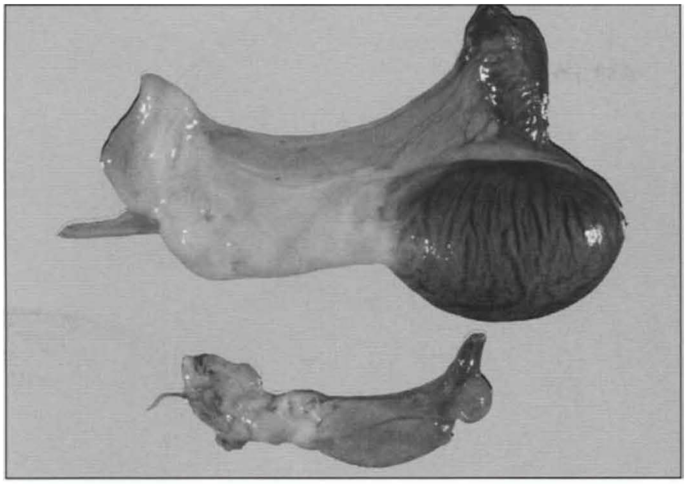

Figure 5.9 Equine **fetal** testis and epididymis (upper) with **physiological gonadal hypertrophy**; testis is dark brown. Testis undergoes atrophy to become the size of the **normal neonatal testis** (lower) before it passes through the inguinal canal.

occurs prior to birth. Many a practitioner and pathologist have been fooled by the apparent brown discoloration of the testicular parenchyma of the neonatal testis (Fig. 5.9).

Anomalies of development

Cryptorchidism

Incomplete descent of the testes and associated structures (cryptorchidism) is one of the most common abnormalities of the male reproductive system, and is the most common genital abnormality of the male cat and horse. Descent of the testes, epididymides, and spermatic cord (including the testicular artery and vein and the deferent duct) is a complex series of events that requires hormonal, constitutive, and nervous control. Individual cases of cryptorchidism may be due to genotypic or environmental causes. Complete testicular descent usually occurs prior to birth in most species, with the exception of the dog.

Maldescent creates several problems. Most cases are presumed to be inherited, and, as such, breeding from affected individuals is not recommended. *Retained testes lack spermatogenesis*, and *fertility may be compromised. Increased rates of testicular neoplasia* are associated with cryptorchidism in several species, most notably the dog. Finally, *testicular torsion* is found almost exclusively in maldescended testes, although the stallion may be an exception.

Testicular (and therefore epididymal) descent occurs in three main stages: *the relative transabdominal migration phase, the intra-inguinal phase, and extra-inguinal migration*. The first phase may be partially controlled by Müllerian inhibitory substance, the second phase requires increased intra-abdominal pressure, and the third involves interaction of androgen, calcitonin gene-related protein, the genitofemoral nerve, and perhaps other factors. The exact mechanisms are yet to be elucidated in domestic mammals, but they no doubt are complex and involve an interrelationship of systemic and local factors. The effects of endocrine disruptors on male development are increasingly important, as multiple anomalies such as reduced anal–genital distance, delayed preputial separation, hypospadias, and ectopic and maldescended testes can all be induced by antiandrogenic and estrogenic chemicals.

In early fetal life, a cranial gonadal suspensory ligament supports the testis. It is retained when there is a lack of exposure to androgen, in which case subsequent development of the *gubernaculum testis* also is impaired. The gubernaculum testis is a gelatinous cord of tissue that extends from the caudal pole of the testis to the inguinal area and it exerts traction on the testis. A mutation in the *GREAT* gene, which is highly expressed in the gubernaculum and may mediate response to hormones, has been associated with intra-abdominal cryptorchidism in humans and, experimentally, in mice.

Diagnostic pathologists are frequently asked to ensure that the tissue removed during cryptorchidectomy was testis. Where the tissue resembles normal testis, there is little challenge, but, all too often, the retained testis has degenerated or is twisted and only a small remnant remains. The most difficult cases are those where necrosis of the testis presumably has occurred and all that remains is scar tissue and hemosiderin- and lipofuscin-containing macrophages. *Anorchia* is very rare and, where possible, should be separated from degeneration or death of a retained testis.

The structural anomalies associated with the failure of the testis to migrate to the scrotum include splenogonadal fusion, retention of the cranial gonadal suspensory ligament, and abnormalities of the gubernaculum and vaginal process.

A *hereditary basis* for cryptorchidism has been established or suggested in all species. Chromosomal abnormalities are implicated in many species including rams, bulls, and stallions. Chromosomal anomalies were detected in humans in 4% of a group of 160. However, a hereditary basis is unlikely in outbreaks of cryptorchidism, and *hormonal and environmental factors* are more likely.

Retained testes in pubescent animals are smaller than their normal counterparts (Fig. 5.10). This is because of the deleterious effect of body temperature on spermatogenesis. The seminiferous tubules are smaller than normal and often present with the "Sertoli cell only" pattern. Germ cells may be recognized in young animals, but in older animals, degenerative changes such as interstitial fibrosis and thickening of basement membranes superimpose on the hypoplastic appearance. In extreme forms, the outlines of distorted basement membranes are seen in a sclerotic tissue. Hyperplastic foci of Sertoli cells occur in some retained testes and these may be sites of development of Sertoli cell tumors. In unilateral testicular maldescent, which is typical, the contralateral testis is hypertrophied.

Cryptorchidism is the most common disease of the reproductive tract in male **cats**, and Persians are over-represented. The failure of testicular descent in cats tends to be unilateral without a bias to one side or the other. The testis can be anywhere along the migration path, although inguinal cryptorchidism predominated in one study.

In **dogs**, cryptorchidism may be an inherited disease (autosomal recessive) in some breeds, although there is some doubt that this is the main cause. Although it is a frequent clinical finding, little is known of the mechanism and features of the condition. There are

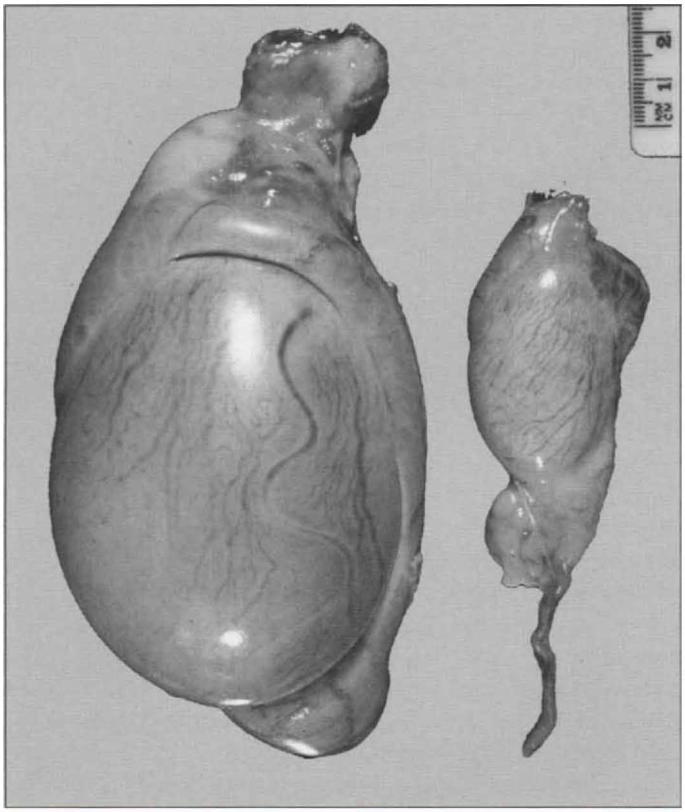

Figure 5.10 Unilateral **abdominally retained testis** (right) from a ram. The contralateral testis (left) was within the scrotum and is more bulbous than normal because of compensatory hypertrophy.

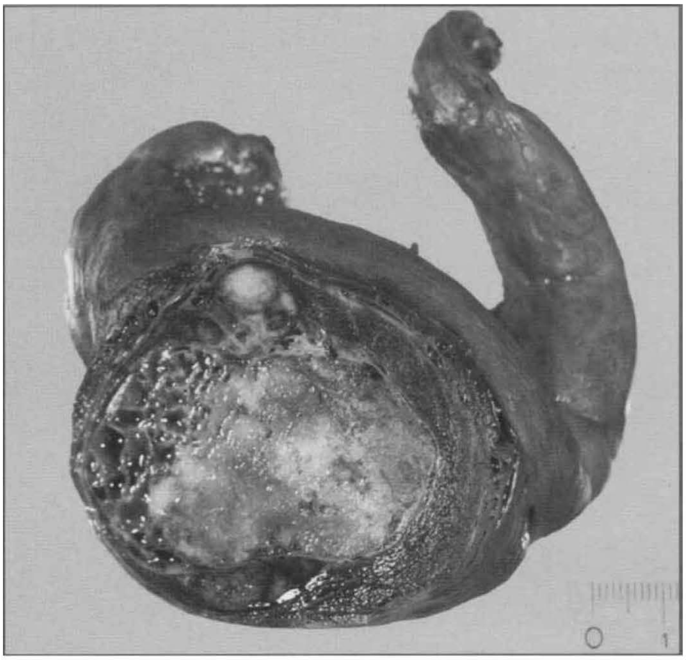

Figure 5.11 **Intra-abdominal testis** of a dog that developed a Sertoli cell tumor. The testis subsequently underwent torsion and venous infarction.

associations of cryptorchidism with several other diseases in dogs. *The association between testicular neoplasia and testicular maldescent is well recognized.* Sertoli cell tumors are the most common, especially in abdominally retained testes. Seminomas are the second most common neoplasm, and they are mostly in inguinally retained testes. Persistent Müllerian duct syndrome in Miniature Schnauzers is associated with unilateral or bilateral testicular maldescent. Testicular torsion usually involves cryptorchid testes – especially if there is a concomitant testicular neoplasm (Fig. 5.11). Other diseases associated with ectopic testes are patellar subluxation, hip dysplasia, penile and preputial defects, and umbilical and inguinal hernias.

Dogs are more likely to have retention of the right testis – perhaps because of a longer pathway for descent of the testis, or a less well-defined gubernaculum on the right. Inguinal testes predominate over intra-abdominal. Testicular neoplasms – Sertoli cell tumor and seminoma – are more prevalent in the right side also. Descent is usually complete by 3 months of age in the dog. Hormonal studies suggest that LH is lower in cryptorchid dogs, and the cryptorchid testis mediates the inhibition of LH secretion.

Cryptorchidism is common in **boars**. There is a hereditary basis, with the trait being recessive, and in the Duroc breed there may be involvement of recessive genes at more than one locus. Abnormal development of the gubernaculum including underdevelopment, excessive growth, and an abnormal location is the main cause of cryptorchidism in pigs.

Cryptorchidism is infrequently reported in **bulls**, but this does not necessarily indicate a low prevalence – because it is easily recognized by laypersons who do not report its occurrence. Retention of the testis and epididymis is mostly in the inguinal region, and occurs about twice as often on the left as compared to the right side. Polled Hereford and Shorthorn cattle are more at risk than other breeds. Little is known of the pathogenesis of cryptorchidism in bulls, although it is believed to be hereditary. The appearance of the cryptorchid testis is similar to that of hypoplastic testes and epididymides. Neoplasia is very rare, with an interstitial cell tumor being reported in a cryptorchid calf.

In **rams**, cryptorchidism is most likely the result of an autosomal recessive mode of inheritance, but it may also be due to a dominant gene with incomplete penetrance. Unilateral maldescent is more common than bilateral involvement, and the right testis is most often retained. Castration of ram lambs in many parts of the world is done by laypersons, and hemicastration is likely in unilateral cryptorchid animals. Some castrated animals have only their scrotum removed, leaving the testes in an "induced cryptorchid" state. Cryptorchidism in sheep has an increased prevalence in polled animals.

Cryptorchidism occurs sporadically in **goats**, mainly involving the right testis. It is a regular feature of the goat polled/intersex syndrome.

There are many reports of cryptorchidism in **stallions**, and the condition is particularly noted because of the aggressive tendencies of stallions as compared to geldings. Testicular retention is usually unilateral, with about equal frequency as to side affected. Abdominal retention of left testes is more common than inguinal; the reverse is the case on the right side. Neoplasia of the retained testis is occasionally seen, with teratomas, seminomas, and Sertoli cell tumors being reported.

Other testicular anomalies

Monorchia is the presence of only one testis. As a general term, monorchism is the result of cryptorchidism, severe unilateral testicular degeneration or agenesis. *True agenesis* occurs when there is a failure of one testis to develop. The differentiation between true agenesis and a cryptorchid with total testicular degeneration is impossible, but true agenesis is considered to be very rare. The presence of *supernumerary testes* or *fusion of abdominal testes* is also very rare.

The presence of testicular tissue outside the testis is reported in pigs, where nodules of tissue are found throughout the peritoneal cavity. In the cat, heterotopic interstitial endocrine cells are reported in the epididymis, and neoplasia of this tissue is reported.

Fusion of the testes to abdominal organs such as the spleen is reported, and is a cause of cryptorchidism.

Accessory or ectopic adrenal tissue is occasionally found in horses and rarely in other species. Most are located in the region of the head of the epididymis and distal spermatic cord (Fig. 5.12).

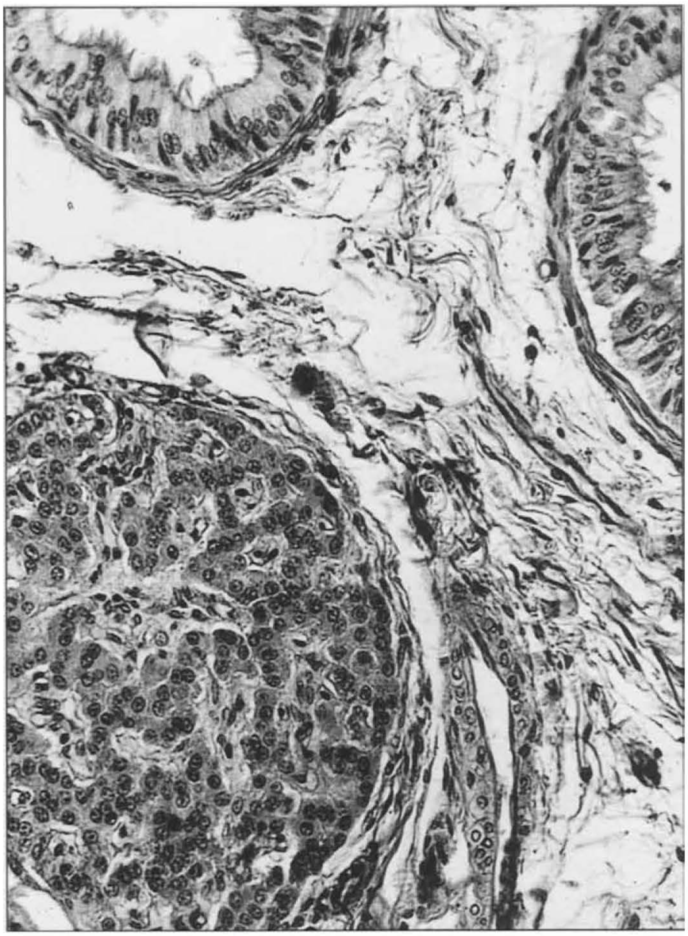

Figure 5.12 Microscopic **ectopic nodule of adrenal cortex** in the epididymis of a ram.

Variations in the shape of testes are described. "Hour-glass" shaped, round, and horizontally placed testes are all reported.

A variety of cystic structures have been described in and around the testis and epididymis. Some arise from the rete testis and others are remnants of mesonephric ducts or ductules, or paramesonephric ducts.

Ductular anomalies

The ducts that transport spermatozoa and fluid from the testis join the intratesticular rete testis to the pelvic urethra. Maturation and storage of spermatozoa occurs in this conduction system. There is a single duct from the efferent ductules to the urethra, and any interruption has potentially catastrophic effects to the fertility of that side. The eventual effect of continuous spermatozoal production and disruption of one of the efferent ductules has a similar outcome.

Many ductular anomalies have minor significance. Melanosis of the epididymis occurs in rams and bulls. Adrenal ectopia, various cystic remnants of the mesonephric and paramesonephric ducts

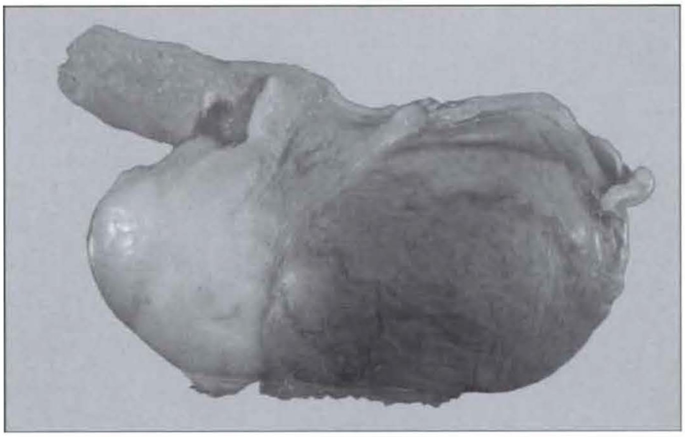

Figure 5.16 **Sperm granuloma** of the **epididymal head** in a dog.

(Figs 5.13, 5.14), and inclusion cysts also are reported in the epididymis. Most are incidental findings and are important as differential diagnoses for epididymitis.

Segmental aplasia of the mesonephric duct is an important condition because it has a profound effect on fertility of the affected side (Fig. 5.15). Segmental aplasia is rare, but further examination of species (such as the cat) in which it has not been reported would no doubt complete the list of species in which it is known to occur. Unilateral aplasia may be an inherited condition. The lack of one part of the epididymis or deferent duct is most likely to be identified if the tail of the epididymis is missing, so it is not surprising that this is the most frequently recognized anomaly. Apart from an absence of the structure, continuous production of spermatozoa results in the complications of spermiostasis, tubular dilation, formation of sperm granulomas, dilation of the mediastinum testis, and testicular atrophy. Examination of the accessory genital glands will usually reveal a smaller vesicular gland on the affected side – presumably because of a lack of trophic stimuli. Hypertrophy of the contralateral testis is also likely.

Sperm granuloma of the epididymal head (Fig. 5.16) is often mistaken for infectious epididymitis. Failure of one or more of the 12–25

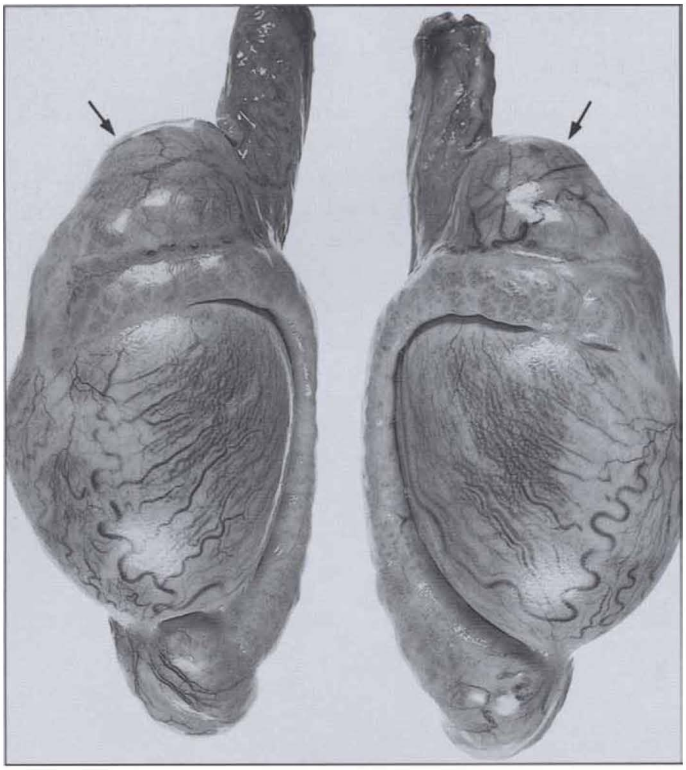

Figure 5.17 Bilateral **sperm granulomas** of the **epididymal head** (arrows) in a goat. Each efferent ductular region, and the head of the epididymis are large and contain sperm granulomas.

efferent ductules to join with the epididymal duct is believed to be the underlying defect. After puberty, the blind-ended ductule(s) fill with spermatozoa and, with spermiostasis, may rupture and/or form a sperm granuloma. The associated inflammation and fibrosis will eventually cause obstruction of other efferent ductules or the epididymal duct. The result will be complete obstruction to flow of spermatozoal-rich fluid and progressive formation of more sperm granulomas. The distal epididymal tissues are reduced in size, the mediastinum testis dilates, and the testis undergoes pressure atrophy. This condition is often misdiagnosed as epididymitis and the potential congenital or hereditary basis for the problem is missed. Sperm granuloma of the epididymal head is a common finding in polled Saanen goats, where they may be bilateral (Fig. 5.17).

Ectopic interstitial endocrine cells and *ectopic interstitial cell tumors* have been reported in the tunica albuginea, mediastinum testis, or spermatic cord of cats.

Many *cystic lesions* have been reported in the tunica albuginea, epididymis, spermatic cord, and adjacent to the accessory genital glands. These are presumed to be remnants or duplications of the paramesonephric and mesonephric duct systems. Remnants of the mesonephric duct include the paradidymis (interna and externa), epididymal cysts, and appendix epididymis. So-called *retention cysts* are very common in the region of the head of the epididymis, especially in rams (see Fig. 5.14). They are usually up to 3 mm in diameter, contain clear fluid, and are lined by epithelium similar to that of the epididymis. The paradidymis is seen proximal to the epididymis in the spermatic cord as one or several small cysts, particularly in neonates. Other cysts, seen particularly in the epididymis, can be microscopic or up to 4 cm in diameter.

Remnants of the paramesonephric ducts include the appendix testis, the uterus masculinus near the accessory genital glands, and, in some cases a completely retained duct that runs beside the testis. Histologically these may have the appearance of a juvenile uterus with prominent musculature and uterine glands.

Variation in testicular and epididymal size

The daily spermatozoa output of the testes is directly and highly correlated to testicular volume, most commonly evaluated using scrotal circumference, for which reference ranges have been established by species or breed. Testes above this range are hypertrophied; those below the range are too small because of atrophy or hypoplasia. *Even experienced pathologists have difficulty in differentiating hypoplastic from atrophic testes in adults.* This is because there are variations in the degree of hypoplasia and, over time, hypoplastic testes may undergo degeneration. The dogma is that in atrophic testes, the ratio of testicular to epididymal weight is reduced since the reduction in size of the testis is greater than the reduction in size of the epididymis. The basement membrane of appropriately fixed atrophic testes is buckled or has a "wavy" outline. In hypoplastic testes, the ratio of the weight of the testis to epididymis is similar to that of normal testes. The size of both is smaller that normal and there are histological features of spermatogenic arrest in tubules that are smaller than age- and breed-matched controls. The best method to be sure that degeneration has occurred is to demonstrate a decrease from normal testicular weight or size over time. In contrast, hypoplastic testes are smaller than normal and remain so. Since pathologists usually must make an assessment based on a single observation, a diagnosis of "small testes" is not necessarily an indication of ignorance; rather, it is an indication of appropriate caution.

Testicular hypertrophy

Enlargement of an otherwise normal testis is rarely a primary disorder. *Secondary or compensatory hypertrophy* is a unilateral condition that indicates an underlying disease such as orchitis or neoplasia in the contralateral testis. It is a well-recognized phenomenon in hemicastrates, and in hypoplasia, cryptorchidism, or atrophy of the contralateral testis (see Fig. 5.10). Hemicastration of prepubertal boars, especially in those younger than 3–4 months, results in dramatic hypertrophy of the contralateral testis. In rams and bulls, hypertrophy appears to occur mostly when the unilateral condition is present during the peripubertal period and is associated with increased FSH production. The increase in size can be up to 100%,

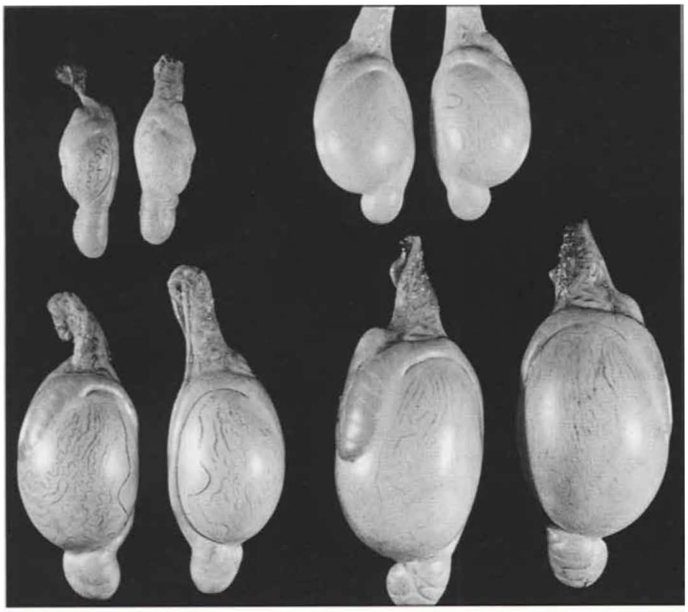

Figure 5.18 Testes and epididymides of four rams of the same age. There is a gradation of **testicular hypoplasia** from severe (upper left) to normal (lower right).

and is due to an increase in the size of Sertoli cells and in the number of germinal cells per Sertoli cell. In some instances there may be an increase in the number of Sertoli cells and spermatogonia, and an increase in diameter and length of seminiferous tubules.

The presence of *dilated cystic remnants and pseudocysts* can also cause, or be confused with, enlargement of a testis. Occlusion of the efferent ductules can lead to dilation of the rete and mediastinum testis and appear as testicular enlargement, although the thickness and fibrous nature of the tunica albuginea makes sudden enlargement of the testis less likely. Adhesions and thickenings of the tunica vaginalis can also appear clinically as testicular enlargements. To the unsuspecting, lesions of the scrotum or its contents are frequently mistaken as testicular enlargement; hydrocele, epididymitis, or the presence of sperm granulomas are examples.

Testicular hypoplasia

Hypoplastic testes have failed to grow to a normal size. *Testicular hypoplasia occurs in cryptorchidism, some intersex conditions, and as an "uncomplicated" disease.* It can be unilateral or bilateral, and the small size is because of a reduction in the amount of the seminiferous epithelium. An affected testis is grossly similar to a normal testis in almost every way, except size (Fig. 5.18).

Hypoplasia is the potential outcome of a large number of different abnormalities that may operate at a systemic or local level, as perhaps occurs in the case of unilateral disease. The small size is theoretically because of an abnormally small number, length, or diameter of tubules, or one or more combinations of these (Figs 5.19A, B and 5.20). Germ cells may be absent, or be present but fail to produce enough spermatozoa. Germ cells may have failed to migrate to the genital ridge in utero, failed to migrate in sufficient numbers, failed to survive, or they may have arrested development, undergo excessive apoptosis, or undergo degeneration at some stage of spermatogenesis (Fig. 5.21).

Studies of hypoplasia have been mostly observational, at the clinical, gross, or microscopic level. Microscopic abnormalities include a total lack of germ cells, arrested spermatogenesis in all tubules, or arrested spermatogenesis that varies from tubule to tubule (low germ cell resistance). Hypoplastic testes with a total lack of germ cells are very small and fail to enlarge from their size at birth. Those testes with arrested development of all tubules fail to progress beyond a certain stage of spermatogenesis.

A deficiency of gonadotrophins is associated with hypoplasia (hypogonadotrophic hypogonadism) in men and mice, but studies in domesticated mammals indicate a normal or raised serum concentration of FSH and LH. Testosterone concentration was lower than normal in some bulls with hypoplasia; in sheep, testosterone and inhibin concentration may be normal.

At the chromosomal level, testicular hypoplasia in animals with a condition resembling Klinefelter's syndrome is recognized. Affected cats, bulls, dogs, pigs, horses, and sheep have an XXY genotype or a mosaicism with XXY chromosomes. The best known of these is the male tortoiseshell or calico cat. In goats of the Saanen breed with the gene for polledness, testicular hypoplasia is seen in genetically female pseudohermaphrodites. A variety of other chromosomal abnormalities have been identified as being associated with hypoplasia.

At the genetic level, hypoplasia is known or suspected to be *hereditary* in the bull, ram, and buck. The exact genetic abnormality

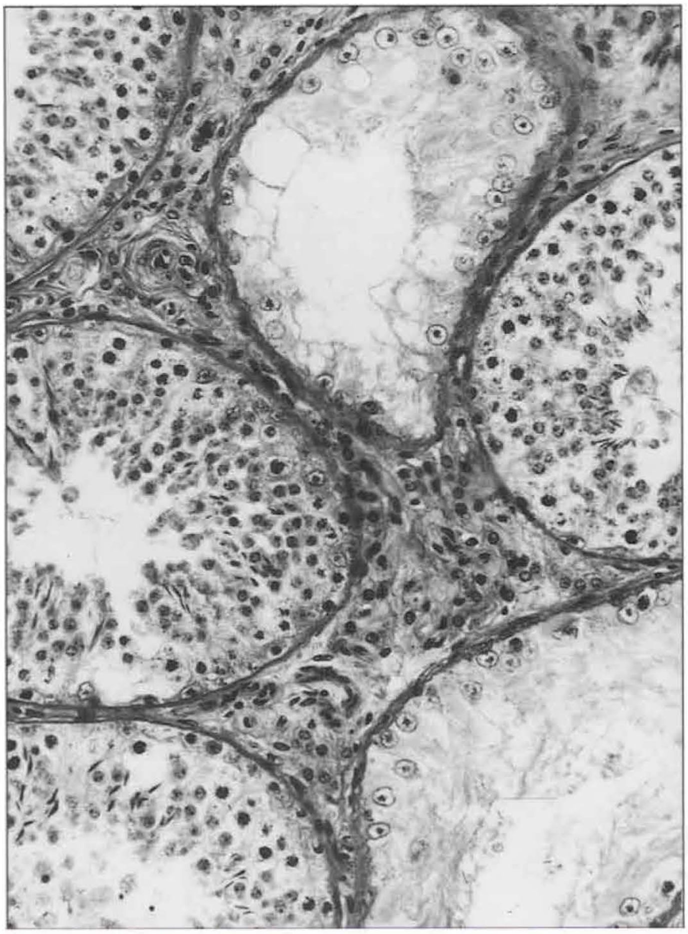

Figure 5.20 Hypoplastic seminiferous tubules adjacent to normal tubules of a bull.

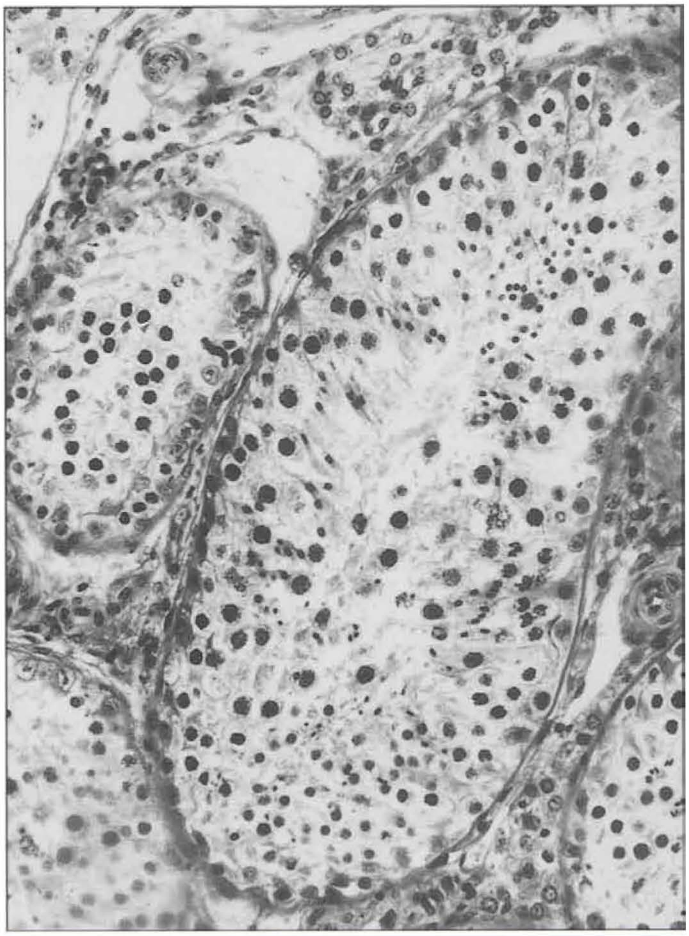

Figure 5.21 Seminiferous tubules of a bull with **testicular hypoplasia**. Tubules have arrested spermatogenesis.

is often not established. There are few studies of hypoplasia in domesticated animals, but there are some special features of the disease in selected species discussed below.

Hypoplasia in bucks

There are several types of hypoplasia recorded in bucks. It is a common abnormality in the polled/intersex (XX sex reversal) syndrome of polled Saanen goats, where the animals are genotypically female but phenotypically male. The testes of affected animals have rudimentary seminiferous tubules. Other sporadic forms of hypoplasia occur, and the cause is not known.

Hypoplasia in bulls

As with other species, testicular hypoplasia in bulls probably is a multifactorial condition. Studies suggest it is hereditary, particularly in the Swedish highland breed, where it has a recessive inheritance with incomplete penetrance. Animals with white body and ears are particularly likely to have hypoplasia. The majority of unilateral hypoplastic testes are on the left side.

The defect in hypoplasia varies from case to case. Some are regarded as a "germ cell weakness," whereby germ cells are present in most seminiferous tubules but there is marked pyknosis of primary spermatocytes. Some are described as having "sticky chromosomes" with the presence of multipolar spindles in primary spermatocytes, or having germinal epithelium that does not progress to spermatogenesis. Other cases of hypoplasia have a Sertoli cell-only pattern or they have some normal and abnormal tubules intermixed, often with affected tubules being in the more dorsal parts of the testis. Despite the various abnormalities observed, there generally appears to be a cessation of spermatogenesis at some stage, with either degeneration or excessive apoptosis of the germinal epithelium.

Hypoplasia in cats

Testicular hypoplasia is a sporadic disease of cats. It is most frequently seen on cryptorchid animals and in cats with a tricolor or calico coloration. Males with tricolor or calico coloration often have an XXY genotype. Affected cats may have no germ cells and markedly hypoplastic testes with small diameter tubules. Chimeric animals may be fertile.

Hypoplasia in dogs

A diagnosis of testicular hypoplasia in dogs is usually made only after azoospermia is found during an investigation of infertility. Hypoplasia cannot be implicated as a cause of azoospermia if the dog has been previously fertile, and can only be considered if acquired azoospermia can be ruled out with certainty. Confirmation of congenital azoospermia because of testicular hypoplasia requires historical information or testicular biopsy after the expected date of puberty.

Congenital azoospermia occurs in some lines of dogs. This suggests a familial or hereditary basis, implicating inbreeding.

Hypoplasia is commonly seen in animals with failure of testicular descent, and in chromosomal abnormalities such as XX sex reversal and XXY syndrome. Offspring of bitches treated with diethylstilbestrol may have hypoplastic testes.

Hypoplasia in rams

Testicular hypoplasia of rams usually is a sporadic disease that may be either bilateral or unilateral. The disease is not well studied. A condition resembling Klinefelter's syndrome, with an XXY genotype is reported. Zinc deficiency has been implicated in some cases.

Various degrees of hypoplasia are recognized, and affected testes may have tubules that, at the extreme are about 90 μm in diameter (normal 160 μm) and are lined by mostly fetal Sertoli cells. An outbreak of gonadal hypoplasia that affected rams born within a short time frame is reported. The affected testes were uniformly small and had a "Sertoli cell-only" pattern histologically. An environmental cause was suspected.

Testicular degeneration

Testicular degeneration is manifested clinically and grossly as atrophy, mineralization, and fibrosis. It usually occurs because of influences external to the testis (see Testicular hypoplasia). There is a seemingly endless list of potential causes, as outlined in Table 5.1. The close interrelationship of the Sertoli cells, interstitial endocrine cells, and germ cells means that insults to any one or several of them eventually affect them all. Even though the insult is external to the testis, the manifestation in the testis is not always bilateral or uniform. The testes of aged bulls frequently degenerate from the ventrum, and those from rams appear to degenerate from the dorsum.

Testes undergoing degeneration are usually reduced in size. In early or rapidly progressing degeneration, the testis is soft and flabby, lacks turgor, and the cut surface does not bulge. Wrinkling of the tunica albuginea may be apparent. With ongoing loss of fluid and reduction in the germinal epithelium relative to the stroma, the result is a small testis of firm consistency. The substance of the testis takes on a darker color that is often brown. Since the epididymis usually is less affected than the testis, it ultimately will appear to be disproportionately large (Fig. 5.22A, B). With continued degeneration and fibrosis, the testis becomes increasingly hard and variable mineralization may occur (Fig. 5.23).

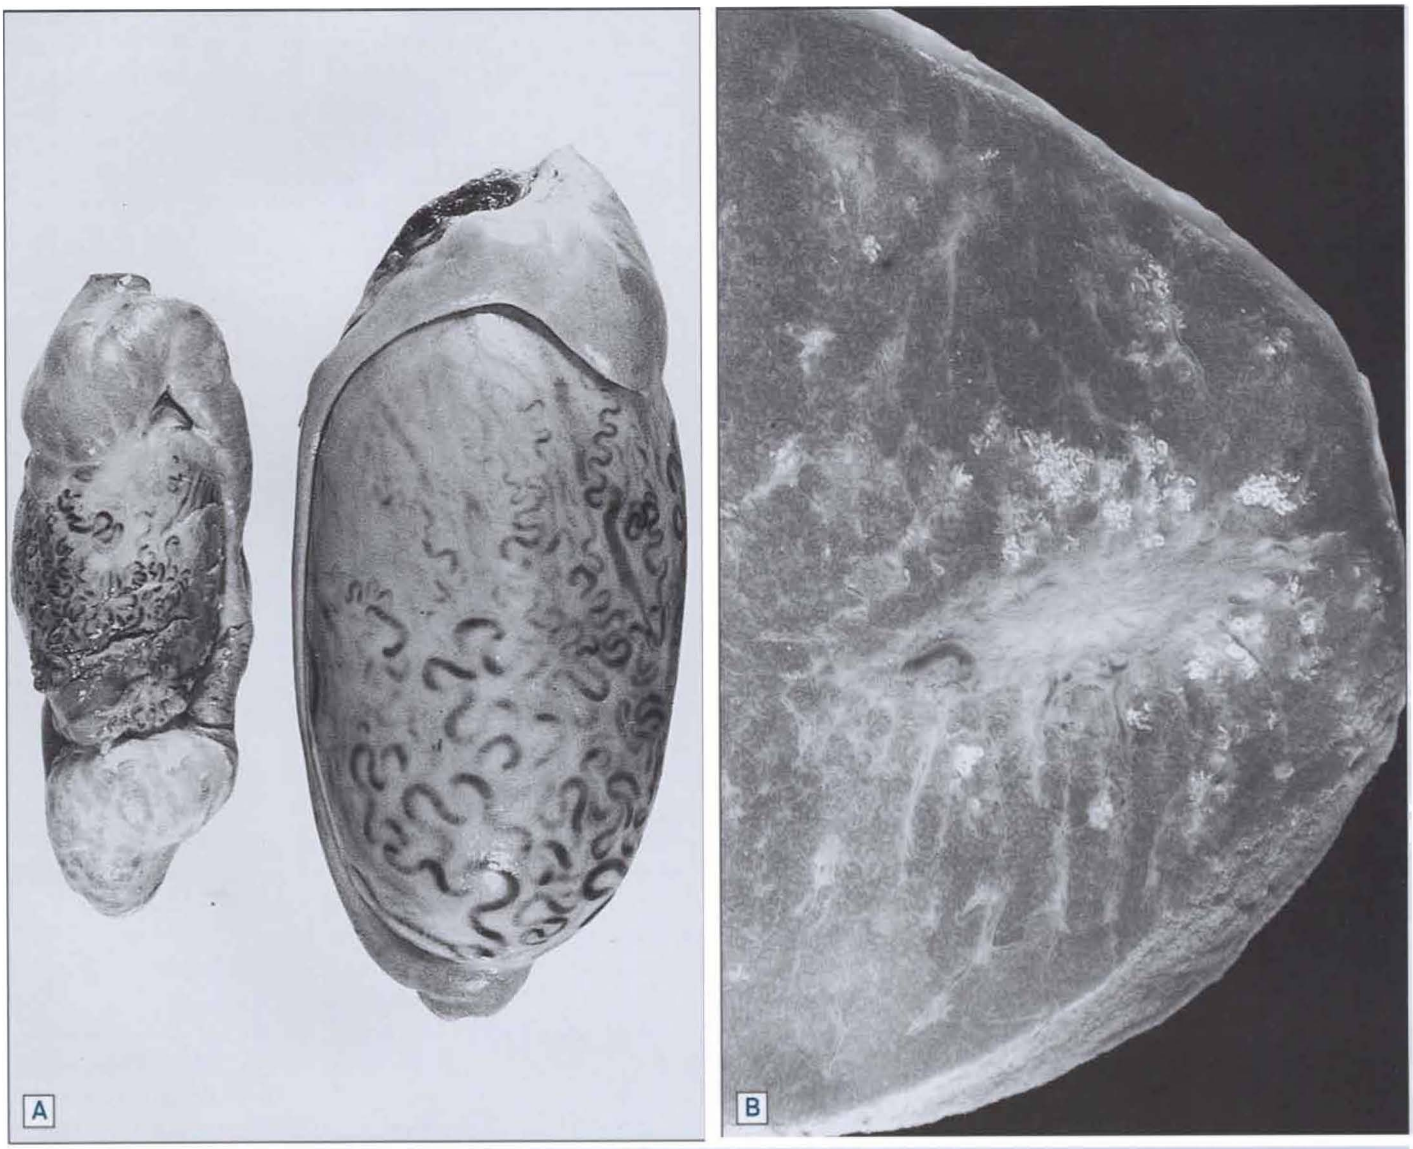

Figure 5.22 **A.** Unilateral **testicular degeneration** in a bull. The epididymis of the atrophic testis appears disproportionately large. **B.** Discoloration (brown) of the testis and mineralization of seminiferous tubules in a bull with testicular degeneration/atrophy.

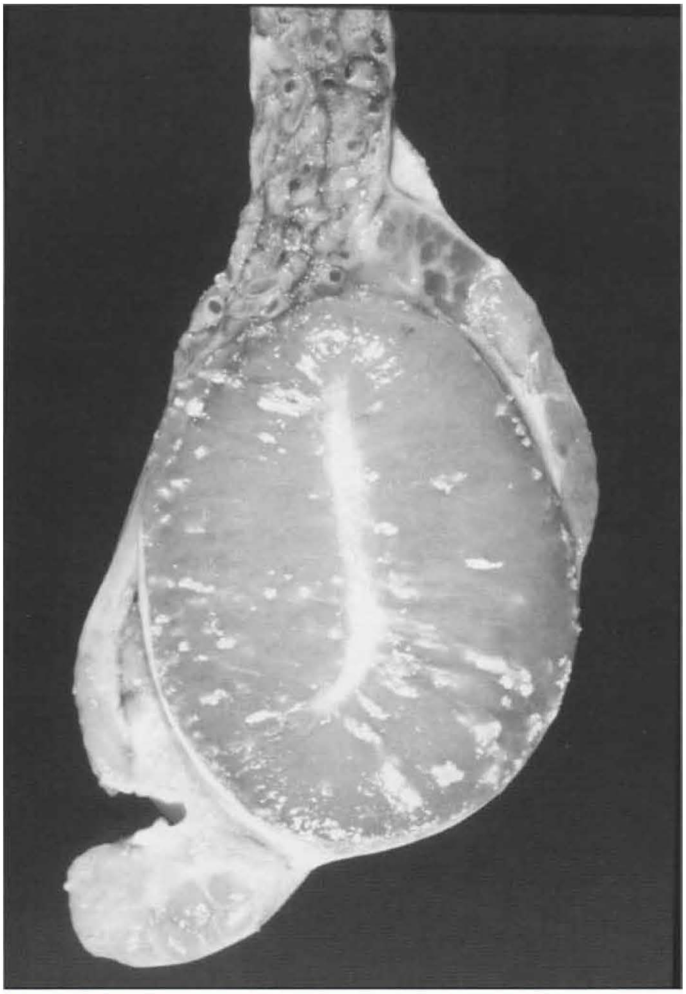

Figure 5.23 Testicular atrophy and resultant darker testicular color, and multifocal mineralization in a buck.

Testicular degeneration may be uni- or bilateral, and *it is assumed that unilateral degeneration is the result of a local event, while bilateral degeneration usually is the result of a systemic problem.*

Histological changes in degeneration (Fig. 5.24A, B) vary in degree, but are relatively stereotypic. In the early stages, Sertoli cells develop either a fine basal vacuolation or a more dramatic vacuolation of the apical cytoplasm. There also is disorganization and exfoliation of germ cells. In some cases there may be failure of release of germ cells from Sertoli cells (spermiation) and spermatozoa are phagocytized by Sertoli cells.

Early changes in the germ cells include failure of maturation of spermatozoa and degeneration of spermatids; many spermatids are necrotic and others produce characteristic spermatidic multinuclear giant cells. When the degeneration is more advanced, the affected areas are more extensive and degenerative changes appear in the precursors of spermatids. Depending on the insult, there may be cytoplasmic vacuolation and nuclear pyknosis, or apoptotic bodies are seen. Progression of the changes results in loss of germinal cells, and eventually, loss of even the resistant Sertoli cells. Basement membrane thickening is a frequent finding, and as a result of shrinkage and collapse of tubules, it becomes wavy and buckled. The PAS stain clearly accentuates the basement membrane change. In ultrastructural studies of the testes of normal bulls and bulls with atrophy or hypoplasia, mean thicknesses of the actual basal lamina were approximately 0.7, 1.5, and 1.0 μm, respectively.

Once-only scrotal heating can cause the appearance of giant cells in degenerate testes and perhaps in the semen. Two types of giant cells, mononuclear giant cells probably derived from pachytene spermatocytes that fail to differentiate further, and multinucleate cells considered to be derived from coalescence of identical spermatids, are observed histologically. Even extremely brief heating, of several minutes only, induces giant cell formation. Such giant cells are seen as early as 6 hours and as late as 7 weeks post-heating, but they seem to be most prevalent at about 1 week. The fate of these cells is unclear. They may disintegrate or pass out of the testis. In addition to giant cell formation, minor increases in testicular temperature in sheep produce a marked accumulation of B-type spermatogonia; histologically this can be demonstrated by the presence of many cells in which mitosis is incomplete.

Granulomas can form in degenerate testes (Fig. 5.25A, B). This and the presence of lymphocytes and plasma cells indicates an immune response to spermatozoa, but complicates the differentiation of simple degeneration from interstitial orchitis. *Osseous metaplasia* sometimes occurs in tubules affected by spermiostasis for a long time.

Mineralization is a common sign of degeneration, and it may involve all or part of one seminiferous tubule, or whole regions (Fig. 5.26). This latter pattern of change is only significant if the testes are to be biopsied, wherein the section may not be representative of the whole.

The basic mechanism of degeneration of the cells that make up the germinal epithelium is presumed to be via *apoptosis.*

The testis is very susceptible to the effects of increased scrotal temperature. Both testicular and epididymal function are altered when intrascrotal temperatures increase. In the epididymis, an increase in temperature reduces mRNA expression of a spermatozoal membrane glycoprotein (CD52) in a testosterone-independent manner. An inability to maintain the testes at a temperature lower than normal body temperatures can occur with pyrexia, increased environmental temperatures, scrotal thickening and hair and wool cover, and by the presence of intrascrotal inflammation or scrotal dermatitis. Varicocele is also implicated in the failure to maintain testicular thermoregulation. The progressive degeneration of maldescended testes is believed to be the result of abnormally high testicular temperature.

Degeneration of the testes with advancing age is a recognized phenomenon. The cause is not fully known but it may be secondary to degenerative vascular lesions within the testis. Old bulls and rams have a diffuse increase in intertubular stroma and a decreased proportion of tubular mass. Other changes include increased thickness of tunics and tubular basement membrane, increased proportion of degenerate tubules, and an apparent increased number of interstitial endocrine cells, which contain increased lipofuscin.

Gonadotrophins are essential for the normal development and function of the reproductive tract. The pathology of *disruptors of endocrine function* is a major focus because of the effects of antiandrogenic and estrogenic substances on male reproduction. Substances that reduce androgen concentrations, such as lead and ethanol, adversely affect spermatogenesis and cause degeneration. Sometimes the degeneration is subtle – such as reducing the number of

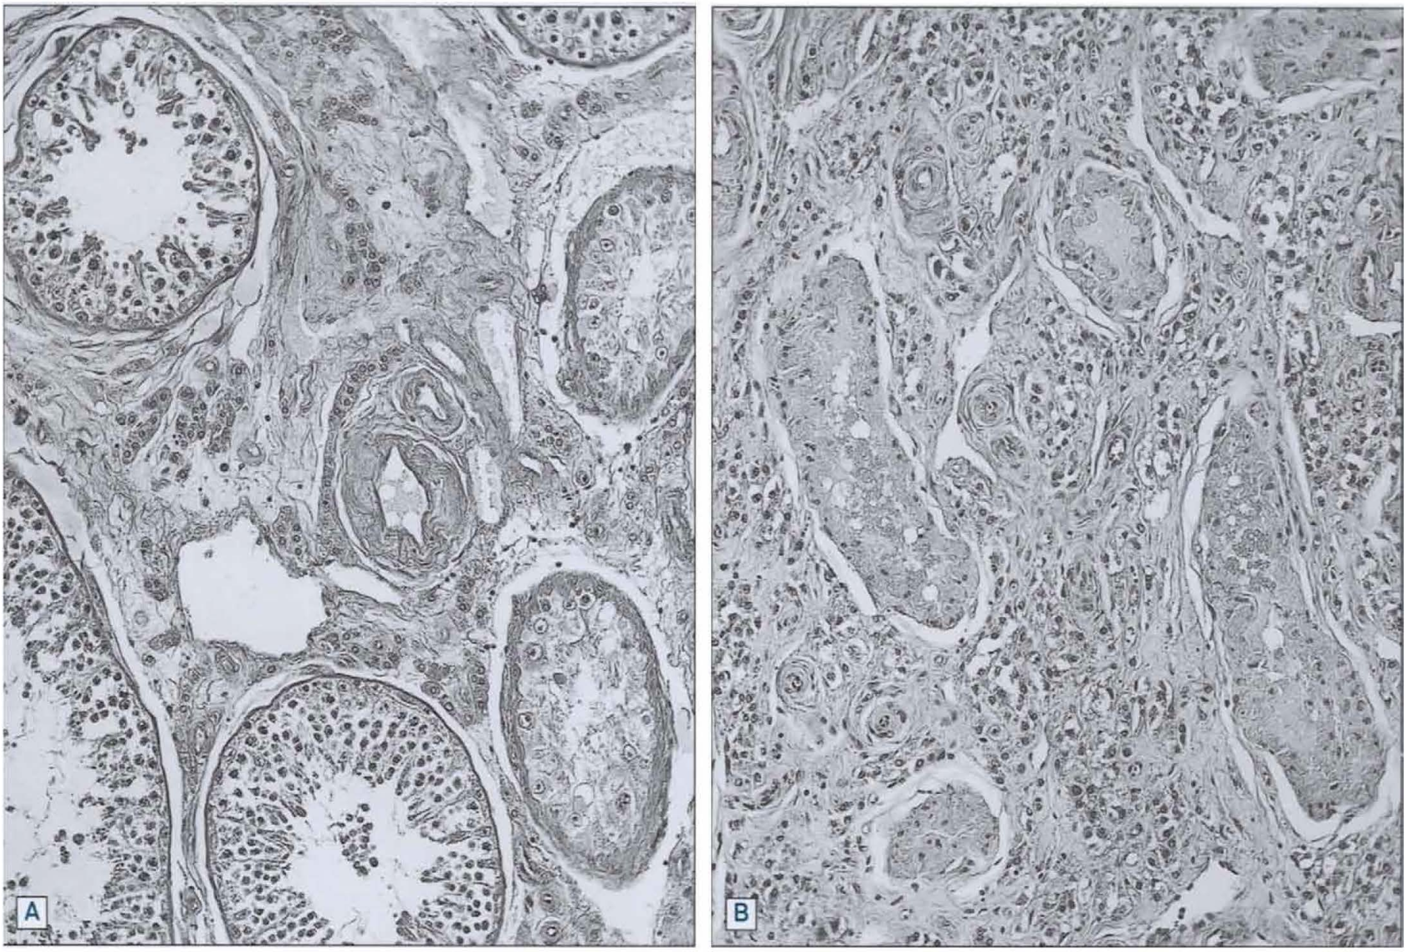

Figure 5.24 Testicular degeneration in a bull. **A.** Tubules are at various stages with changes that include a Sertoli cell only pattern, reduced spermatogenesis, and buckling of basement membranes. Hyalinized blood vessels are in the interstitium. **B.** More advanced degeneration with hyalinized tubules and depletion of both germinal and Sertoli cells.

spermatids. Drugs and chemicals (phenobarbital, DDT) that stimulate the hydroxylases that reduce testosterone activity also can create antiandrogenic effects.

Some *directly acting toxicants* are known in domesticated mammals. These may be derived from plants, or from other environmental or therapeutic sources. Biotransformation of such compounds can occur in the testis, as those formed elsewhere may not attain significant concentrations in the testis. The toxicant may affect any one or several of the cell types, including the Leydig cells, Sertoli cells, spermatogonia, spermatocytes, spermatids, spermatozoa, or the epididymal tissues.

Interstitial endocrine cell toxicants, as expected, affect testosterone production. Ketoconazole, ethanol, acetaldehyde, and cannabinoids are examples. Their effects include alteration of Sertoli cell function and maturation of germ cells, especially pachytene spermatocytes and spermatids.

Direct Sertoli cell toxicants will have detrimental effects on the blood–testis barrier, orientation and translocation of germ cells, hormonal and nutritional support of germ cells, and phagocytosis of residual bodies. The targets for toxicants include the actin filaments, intermediate filaments, and microtubules. Cytochalasin disrupts actin filaments, acrylamide disrupts intermediate filaments, and colchicine, vinblastine, and vincristine affect microtubules. Fortunately, many of these drugs, when used at therapeutic doses, have a temporary effect that is reversed when therapy ceases.

Effects seen microscopically include vacuolation or swelling and germ cell changes. Failure of spermiation can occur.

Toxicants that affect the germ cells are those that are used to prevent rapid mitotic division, and the spermatogonia are the major targets. Adriamycin and cyclophosphamide are examples. Damage by these compounds to the genetic composition of stem cells will also have effects on the later stages of development, up to spermatozoa. Toxicants of the other germ cells are little recognized in domestic species, although in rodents, ethyl glycol alkyl ethers affect spermatocytes, nitroimidazoles affect spermatids, and compounds that impinge on energy metabolism affect spermatozoa. Damage to various stages causes apoptosis, with a rapid uptake of the detritus by Sertoli cells. Within 48 hours, there may no longer be evidence of apoptosis – just the appearance of "maturation arrest."

Toxicants can also affect the efferent ductules and epididymis and/or the spermatozoa in transit. The difficulty with investigating efferent ductular toxicosis is separating the effect due to alteration in testosterone concentration, and direct toxic effects. Substances that affect the efferent ductules include cyclophosphamide, methyl chloride, and reserpine. Such toxicants decrease spermatozoal concentration and cause spermiostasis, sperm granuloma formation,

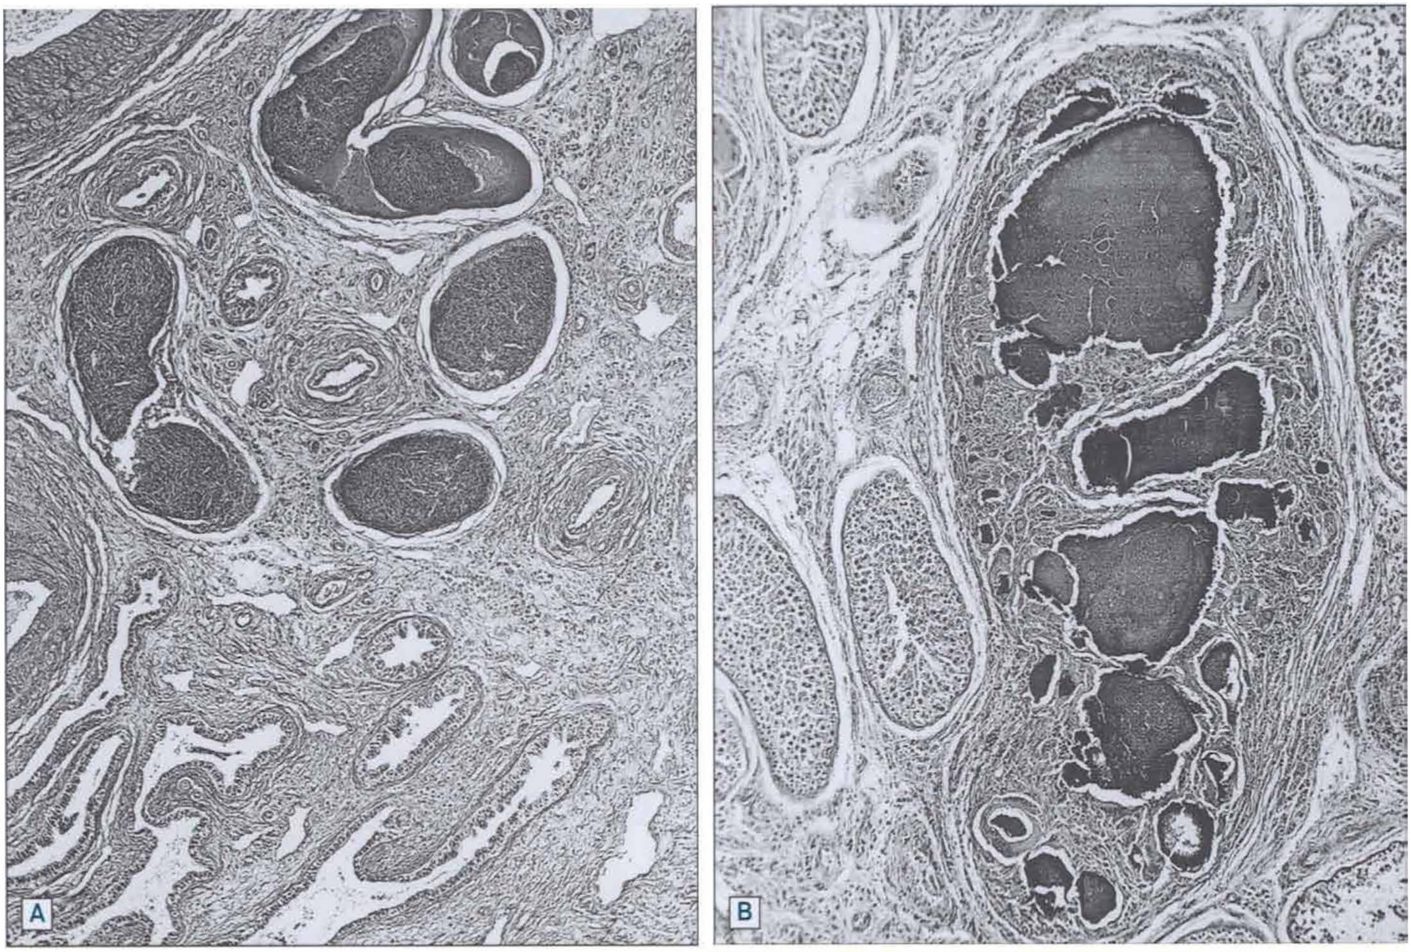

Figure 5.25 **A. Spermatozoal stasis** in remnants of seminiferous or straight tubules near the mediastinum testis. **B.** Sperm granuloma in a focus of spermatozoal stasis in the testis of a bull.

and necrotic and degenerative changes to the epithelium. Several have direct effects on spermatozoa in the ducts.

There are few reports of *direct viral infection* and their effects on spermatogenesis. However, *Porcine reproductive and respiratory syndrome virus* replicates in germ cells, alters spermatogenesis, and induces apoptosis. *Canine distemper virus* infection of dogs can cause testicular degeneration.

Inflammation of the testis and epididymis

Orchitis

Apart from bulls in areas endemic for *Brucella abortus* or tuberculosis, orchitis is a rare and sporadic disease in domesticated animals. *The vast majority of cases diagnosed clinically as orchitis are actually epididymitis* (see below). Focal accumulations of lymphocytes are occasionally seen in the testes of most species as incidental findings (Fig. 5.27). Lymphocytic (or nonsuppurative) inflammation is seen in some infertile animals; an immunological pathogenesis is invoked after it was demonstrated that immunization of guinea pigs and bulls with spermatozoa induced inflammation of the rete testes. Efferent ductules are also involved experimentally.

Orchitis as the primary and severe disease has historically been attributed to brucellosis or tuberculosis. Tuberculous orchitis is a multifocal granulomatous disease that is much less common now because of eradication in many countries. Brucellosis is similarly reduced in

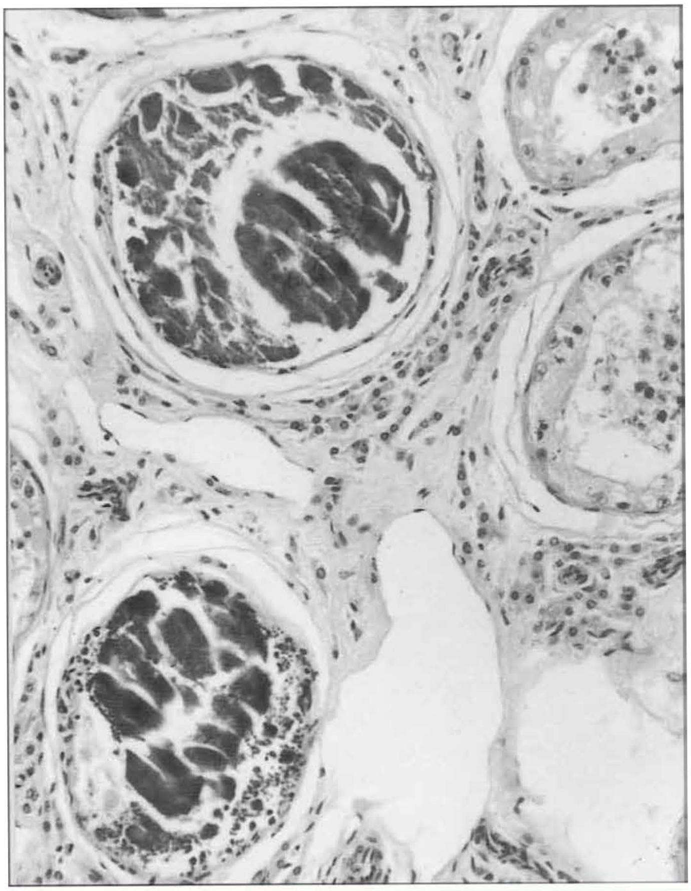

Figure 5.26 Mineralization of seminiferous tubules in the testis of a bull with testicular degeneration.

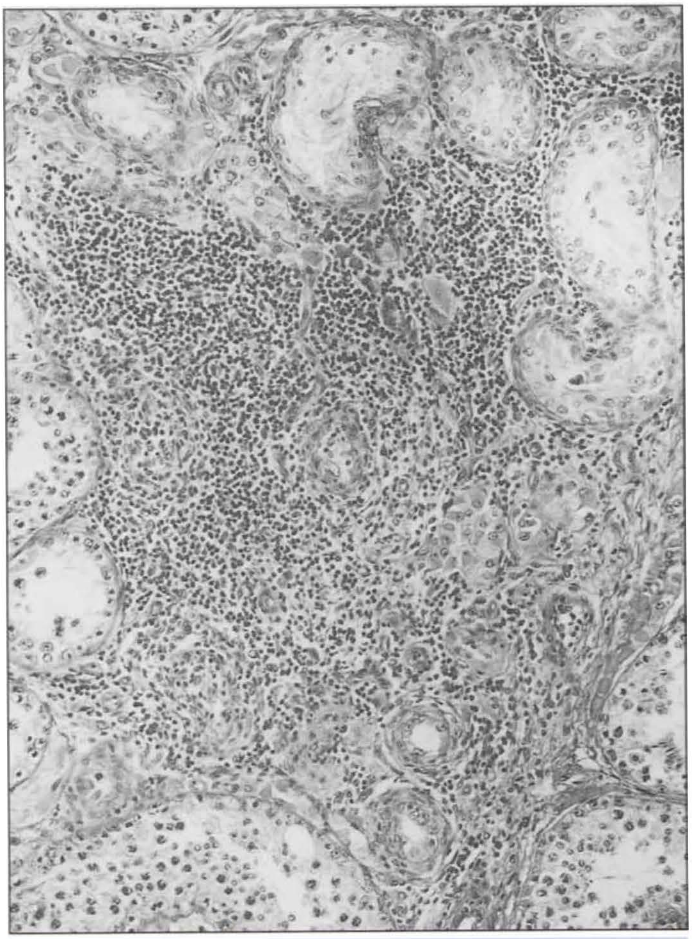

Figure 5.27 Focal interstitial accumulation of lymphocytes with seminiferous tubular degeneration in a stallion.

prevalence. *Brucella abortus* (bulls), *Brucella suis* (pigs), *Brucella canis* (dogs), and *Brucella melitensis* (goats) can cause orchitis as a dominant change. However, epididymitis is often the primary manifestation.

Orchitis occurs sporadically in cats with feline infectious peritonitis, in rams and bucks with *Corynebacterium pseudotuberculosis*, in pigs with *Burkholderia pseudomallei,* and in stallions with migrating larvae of *Strongylus* spp. nematodes. Sporadic infection with other bacteria will no doubt occur from time to time. The relative isolation of the testis suggests that infection with the various agents is mostly hematogenously derived, or occurs by direct penetration.

Orchitis has been divided into three major categories: interstitial orchitis, intratubular or granulomatous orchitis, and necrotizing orchitis.

Interstitial orchitis

Interstitial orchitis may not be recognized macroscopically, but histologically it is characterized by *lymphocytic infiltration of intertubular stroma, with concurrent or subsequent fibrosis* (Fig. 5.28). In bulls, small mononuclear infiltrates are frequently observed adjacent to seminiferous or rete tubules or efferent ductules of otherwise normal testes. Such foci may be of infectious or immune origin, the latter being in response to antigen leaking from a damaged tubule. In stallions, interstitial lymphocytic foci, often perivascular, are particularly common and occur in areas of tubule degeneration and vasculitis. Foci of lymphocytes in cats are considered an age-associated change.

Intratubular orchitis

Intratubular orchitis probably results from *ascending infection.* Macroscopically, solitary or multiple white–yellow foci of up to ~1 cm in diameter are seen. Histologically, the tubule outline is retained in the affected area, but the seminiferous epithelium is obliterated and replaced by numerous macrophages and multinucleated giant cells that surround neutrophils and debris (Fig. 5.29A, B). The pathogenesis of this granulomatous orchitis is comparable to sperm granuloma formation in the epididymis. Sertoli cell hyperplasia and mineralization may accompany these changes.

Necrotic orchitis

Necrotizing orchitis is characteristic of *brucellosis* but may result from other infections, or conditions causing severe trauma or ischemia of the testis. Severe periorchitis may reduce blood supply to the testis so that it dies and becomes a necrotic mass encased within the markedly thickened tunics. Necrotic areas are dry, yellow, often laminated, and slightly mineralized. The histological picture is ultimately one of coagulative necrosis bordered by fibrosis and inflammatory cells. Abscessation and fistulation through the scrotum may accompany necrotizing or other forms of orchitis.

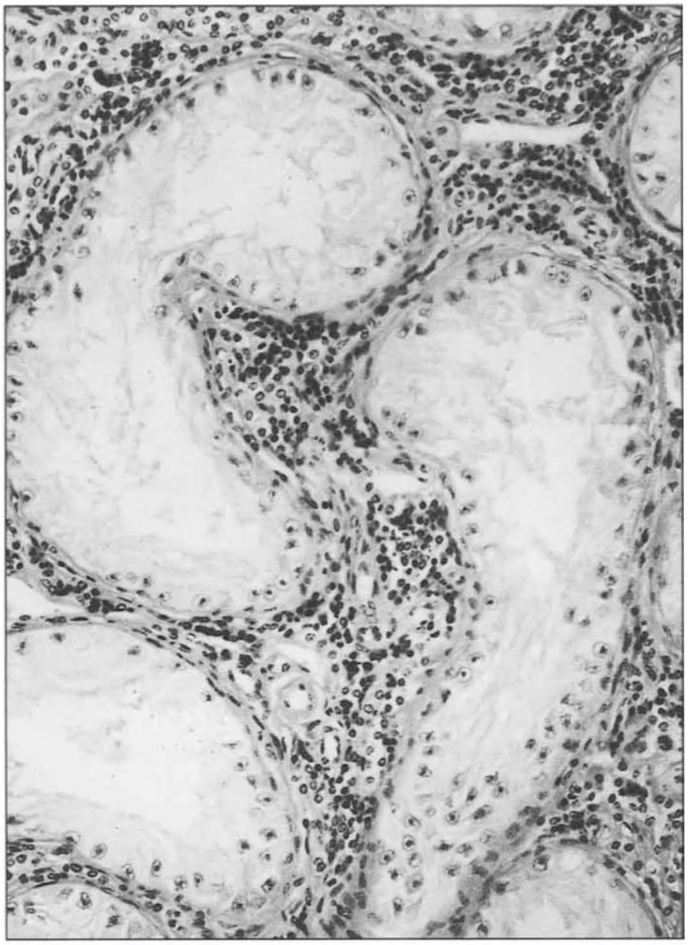

Figure 5.28 Lymphocytic infiltrates in the interstitium of a bull with **interstitial orchitis** and degeneration of seminiferous tubules.

Many infectious agents have been isolated from testes or semen of animals with orchitis, but the significance of many and perhaps most isolates is unclear.

Orchitis in bulls

In bulls, viruses have been isolated from testes or semen, but changes in the testes are observed in association with only some of them. Persistent infection with *Bovine viral diarrhea virus* causes spermatozoal defects, but no distinct histologic lesions in the testis. Severe interstitial orchitis and testicular degeneration associated with inflammation of spermatic arteries occurs in malignant catarrhal fever. In experimental bluetongue virus infection in bulls, interstitial orchitis is also associated with arteritis. Clinical orchitis and aspermatogenesis have been observed in association with enteroviral infection, but lesions are not described. A focal nodular orchitis may be observed in lumpy skin disease of bulls.

Orchitis caused by *Brucella abortus* occurs in regions of endemic **bovine brucellosis**. The live vaccine strain (strain 19) is also capable of producing the lesion. In most instances, the orchitis is acute and the lesion is irreversible. It may be unilateral but affected animals are sterile. The scrotum swells and is hot and doughy due largely to inflammatory changes in the tunics and to a lesser extent in the epididymis (Fig. 5.30). Swelling of the testis is limited by the inability of the tunica albuginea to stretch, and any swelling constricts venous and then arterial flow causing infarction. The cavity of the tunica vaginalis is distended with fibrinopurulent exudate. Scattered yellow foci of necrosis coalesce to produce total testicular necrosis. Sequestration by inflammation and thickening of the tunica soon follows. Sometimes the necrotic parenchyma liquefies and the organ then is a pus-filled cavity surrounded by a thick connective-tissue capsule. Rupture may occur but is unusual. Occasionally, the necrotic foci may not expand and coalesce but rather remain as dry areas of necrosis surrounded by a thick layer of fibrous tissue.

Microscopically, the inflammatory involvement of the tunics is similar to any serous membrane with organization resulting in adhesions between the parietal and visceral layers. These adhesions may be extremely dense. Within the testes, the infection appears to progress along the lumen of the seminiferous tubules. The seminal epithelium becomes necrotic and desquamates. Large numbers of the organisms are visible in the lumen, especially when stained by the modified Ziehl–Neelsen method. At the early stage, a variety of leukocytes invade the interstitial tissues and form cuffs about the tubules. The tubules and the interstitial tissues then become necrotic. There is often focal necrotizing epididymitis complicated by the development of sperm granulomas.

Tuberculous orchitis in bulls is an uncommon lesion, even in areas of endemic infection. The testis is less frequently involved than the epididymis or tunics. The granulomatous response to the tubercle bacilli is similar to the granulomas that occur to spermatozoa. Involvement of the testis may be either miliary or regional. In the miliary form, small or large caseous and mineralized foci are irregularly scattered throughout the testes but may spare the epididymis entirely. Broad bands of caseous necrosis radiate out from the rete testis in the more regional or diffuse form, and the epididymis is usually involved. This distribution is due to the extension of the chronic tuberculous process within the seminiferous tubules. The path of infection in such cases is probably intratubular from a primary epididymal lesion.

Other bacteria causing orchitis in bulls, sometimes in association with overt abscessation, include streptococci, staphylococci, *Arcanobacterium pyogenes*, *Escherichia coli*, *Histophilus* spp., and *Salmonella* spp. *Actinomyces bovis*, *Actinobacillus* sp., and *Nocardia farcinica* may also cause bovine orchitis. In nocardiosis, the lesions are at first nodular but ultimately transform the whole testis into an abscess, the capsule of which is the tunica vaginalis.

Infection of bulls with *Chlamydophila* spp. causes orchitis, and in field cases focal granulomatous lesions have been observed. The spontaneous occurrence of orchitis and epididymitis has been described in a bull with *Mycoplasma* sp. infection.

Orchitis in boars

Pigs experimentally infected with *Porcine rubulavirus*, a paramyxovirus that causes "blue eye," may develop orchitis and epididymitis. The virus targets the head of the epididymis where it causes interstitial inflammation and sperm granulomas. Interstitial fibrosis is seen in animals that recover. Viral antigen is seen in the epithelial cells. Seminiferous tubular degeneration and interstitial orchitis occur in some animals. *Suid herpesvirus 1* infection (pseudorabies, Aujeszky's disease) may cause edema of the scrotal region, but

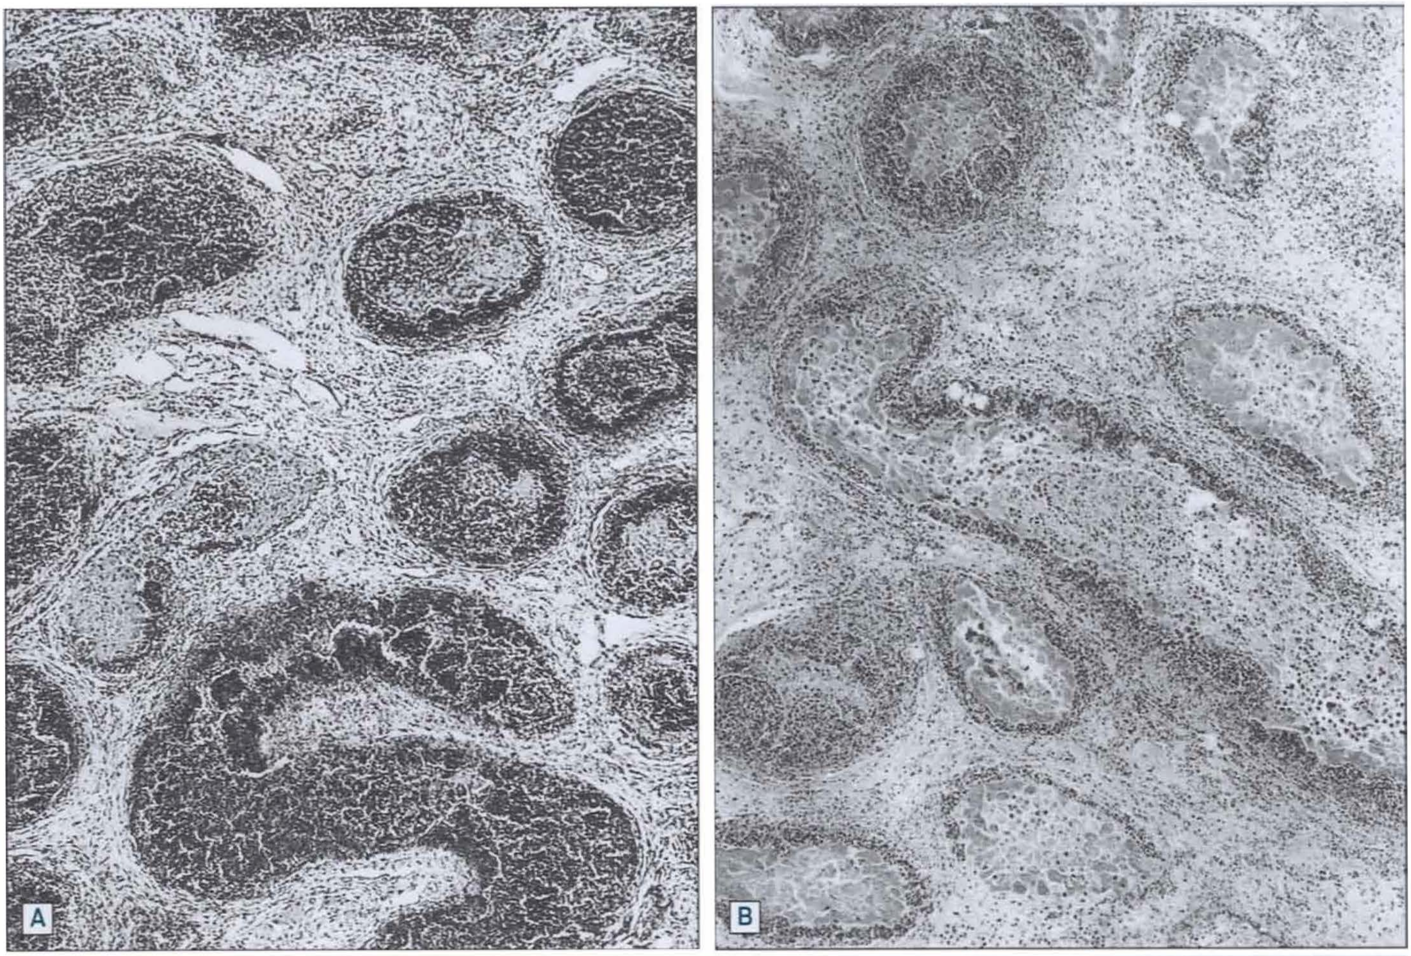

Figure 5.29 Orchitis in a bull, caused by *Brucella abortus*. **A.** The inflammatory reaction is predominantly intratubular. **B.** Necrosis of tubules and inflammatory infiltrates of leukocytes, fibrin, and edema.

results of experimental infection have varied. Viral replication occurs in the serosa after intratesticular inoculation; exudative periorchitis results. Intratesticular inoculation of boars with porcine parvovirus caused testicular degeneration. Enteroviruses and parvovirus have been isolated from semen.

Orchitis caused by *Brucella suis* results in multiple abscesses rather than confluent necrosis. Some cases have fibrinopurulent and hemorrhagic periorchitis. Abscessation develops in the epididymis as well as in the testis; there is central caseation surrounded by a zone of epithelioid macrophages, and these in turn by a broad connective-tissue capsule infiltrated by leukocytes.

In some tropical countries, orchitis caused by infection with *Burkholderia pseudomallei* occurs in boars and other small domestic animals. Lesions may also be found in the vesicular glands (seminal vesicles), prostate, and other organs. Extreme enlargement of the testis due to accumulation of purulent exudate may occur. The main histological lesion is multifocal caseous necrosis with marked mononuclear cell infiltration and encapsulation by much fibrous connective tissue. Severe testicular degeneration accompanies orchitis. Other organisms isolated from boars with orchitis include *Arcanobacterium pyogenes, Streptococcus zooepidemicus*, and *Streptococcus equisimilis*.

Orchitis in stallions

In stallions, mild interstitial orchitis is common. Similar lesions may be part of generalized vascular involvement in equine viral arteritis. Infarcts may also occur in equine infectious anemia. Orchitis can occur as part of systemic disease, and is reported in glanders (*Burkholderia mallei*), and as an acute suppurative, sometimes abscess-forming orchitis in infection with *Salmonella abortus-equi, Streptococcus equi*, and *Streptococcus zooepidemicus*. Focal lesions due to the larvae of *Strongylus edentatus* may be seen in the testis, tunics, and epididymis, especially of young horses. Cryptorchid testes are more commonly affected. Hemorrhagic 2 mm wide tracts containing the migrating larvae are seen. The histological lesions are initially hemorrhagic and then eosinophils infiltrate. *Halicephalobus gingivalis* can cause granulomatous orchitis as a consequence of systemic spread. A pseudocyst, or fluid-filled cavities that have no epithelial lining, is reported in a horse as a sequel to fibrinonecrotic orchitis. The lesion was associated with trauma and secondary infection with *Streptococcus zooepidemicus* occurred.

Periorchitis in horses occurs as part of generalized septic disease, and as a complication of trauma, penetrating injury, or surgery.

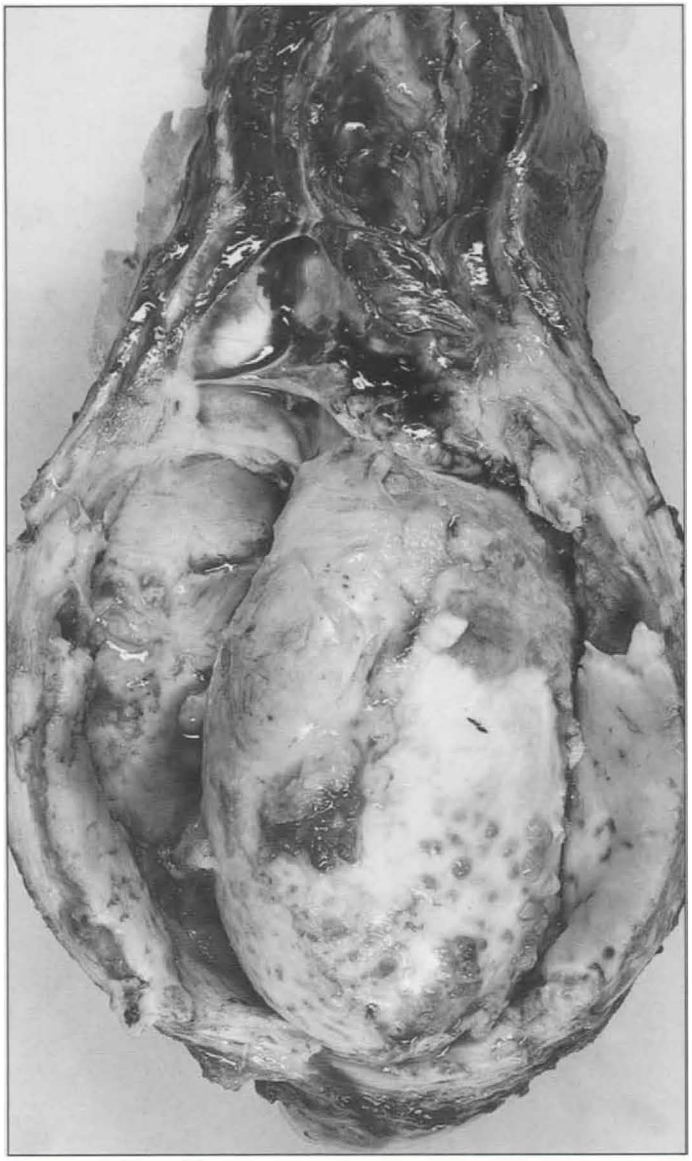

Figure 5.30 Orchitis and periorchitis in a bull, caused by *Brucella abortus*. Fibrin is adherent to tunica vaginalis, epididymis, and testis.

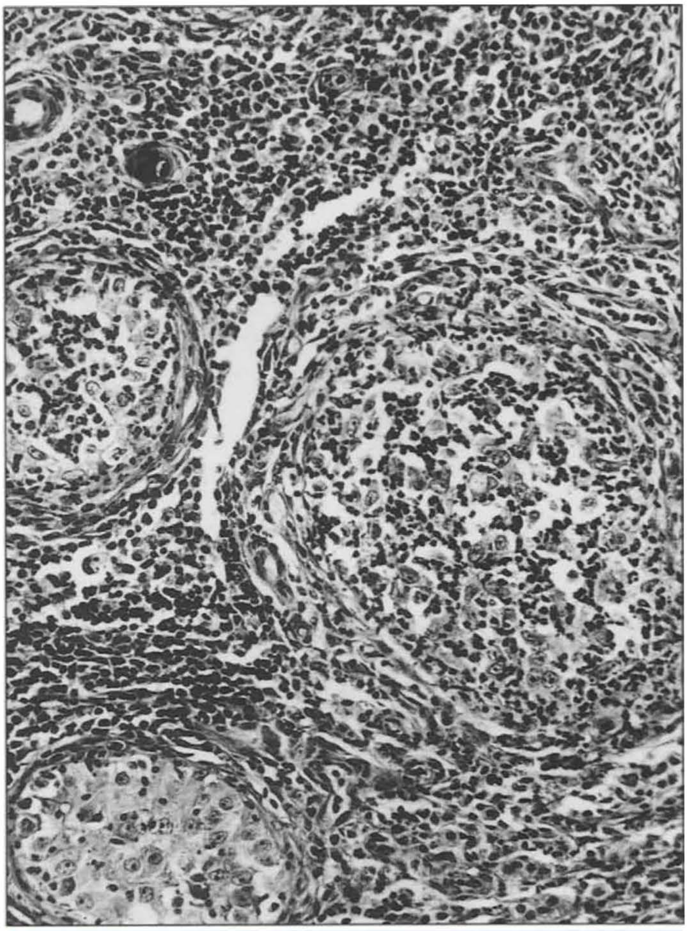

Figure 5.31 Orchitis in a dog, caused by *Escherichia coli*. There are interstitial and intratubular infiltrates of macrophages, neutrophils, and lymphocytes.

Orchitis in small ruminants

Nodular orchitis occurs in sheep pox, and chronic interstitial orchitis, but not epididymitis, has been observed in rams infected with the *Visna/maedi virus*. Sporadic testicular abscesses result from infection with *Arcanobacterium pyogenes* and *Corynebacterium pseudotuberculosis*. In bucks, orchitis, which in many respects resembles brucellosis in bulls, may result from infection with *Brucella melitensis*. Orchitis also occurs in breeding goats as a component of besnoitiosis. Orchitis in rams occurs mostly in association with epididymitis.

Orchitis in dogs and cats

In dogs, orchitis is usually accompanied by epididymitis. Intranuclear and cytoplasmic inclusions are found in the Sertoli cells in mature dogs with distemper. The majority of seminiferous tubules degenerate, and inflammation occurs in a few tubules. Penetrating wounds of the scrotum may occasionally be implicated in the pathogenesis of epididymoorchitis in the dog, but the commonest route is by reflux along the deferent duct from the bladder, urethra, or prostate of infection, chiefly by *Escherichia coli*, *Proteus vulgaris*, and other miscellaneous organisms. An acute inflammatory response in either the epididymis or testis is usually suppurative, with the formation of one or more abscesses (Fig. 5.31). The tunica vaginalis may be involved by extension of the inflammatory process, and fistulation through the scrotal skin to the exterior may occur. Alternatively, dogs will self-traumatize the scrotum and cause a fistula to develop. Acute inflammation usually is centered on the ducts, with degeneration and desquamation of the epithelium, and edema and mononuclear cell infiltrates in the surrounding stroma. Healing occurs with dense scarring, which in the epididymis will cause some tubular obstruction with spermatocele formation. Subacute and chronic inflammatory lesions present no special features. The affected testis is usually firm, small, and irregular, although the epididymis may be enlarged and woody. Lymphocytes and plasma cells now predominate and fibrosis is well developed. Neutrophils predominate in the lumen of the epididymal tubules.

Other bacterial causes of orchitis in dogs are *Brucella canis* and *Burkholderia pseudomallei*, both of which are associated with epididymitis (see below). A familial occurrence of interstitial, lymphocytic orchitis, associated with testicular atrophy and reduced fertility, has been observed in inbred Beagle dogs with lymphocytic thyroiditis; immune factors have been implicated.

Orchitis in **cats** is very rare and may be a manifestation of feline infectious peritonitis. Periorchitis is also a presenting complaint in feline infectious peritonitis and in traumatic injury to the scrotum; orchitis can be a sequel to these conditions.

Epididymitis

Inflammation of the epididymis is one of the more common inflammatory diseases of the genitalia, but frequently it is diagnosed clinically as "orchitis." Regardless of cause, damage to the epididymal duct is complicated by the formation of sperm granulomas and subsequent development of epididymitis. The exception is in prepubertal animals where there are no spermatozoa; in these cases, true abscesses occur. Epididymitis in the absence of sperm granulomas is possible in adults, but it usually is a subclinical or early event.

Epididymitis is often *infectious*, and infectious disease frequently causes a spectrum of lesions, including inflammation of the accessory genital glands. The effects of epididymitis are so much more dramatic than prostatitis, vesicular adenitis, or ampullitis that these latter manifestations are often overlooked. *Sterile epididymitis* does occur, and is caused by congenital ductal anomalies, adenomyosis, trauma, and the reflux of urine.

Bacteria cause most infections of the epididymis, although viruses such as *Equine arteritis virus* and others are reported to induce epididymitis.

Primary infection with *Brucella* spp. in each species results in epididymitis. *Brucella ovis*, *B. canis*, *B. melitensis*, and *B. suis* are especially virulent for the epididymis. It is assumed that the infection is systemic and the bacterium localizes in the epididymis.

Direct infection of the epididymis by penetrating injury is a rare event. Secondary infection from periorchitis, or peritonitis is an occasional possibility.

Almost all species develop infection of the epididymis by the ascending route. This has been studied in the ram where *Actinobacillus seminis* and *Histophilus somni* (*Haemophilus somnus/Histophilus ovis*) are common isolates. While the exact mechanism is not known, it seems that preputial organisms migrate to the accessory genital glands and infect the epididymis by retrograde movement. The privileged environment of the lumen of the epididymal duct allows the organisms to infect the organ and incite damage. The formation of sperm granulomas means that the reproductive potential of the affected side is lost. Complete return to normal is rare. In the dog, the sequel of self-trauma of the scrotum, and systemic affects of infection with endotoxin-producing bacteria such as *Escherichia coli* further complicate epididymitis by causing systemic illness.

Local immunity to prevent epididymitis is not likely to be achieved in the short term. The epididymis has no natural local immune system of antigen receptors, nor known recirculation of immunocytes, and no local plasma cell population. Some aggregates of lymphocytes are occasionally seen in otherwise normal animals. After infection, the epididymis must develop a local immune system, but unfortunately, the damage is usually so extensive, and the sequel so severe, that the response is too late. Even so, the epithelial cells do have the ability to express MHC I and II, and lymphocytes and plasma cells can be recruited after challenge.

Once initiated, the course of epididymitis is variable. The acute stage with edematous enlargement may be followed by abscess and sperm granuloma formation, sometimes with perforation, periorchitis and peritonitis, and increasing fibrosis.

Macroscopically, an increased epididymal size and dissymmetry in shape is apparent especially in unilateral cases in comparison with the contralateral side. Fibrinous and then fibrous adhesions may be present between affected epididymis and adjacent tunics. Consistency will depend on duration of inflammation and the development of sperm granulomas. In chronic epididymitis, the marked increase in fibrous tissue both within the epididymis and between the epididymis and tunics results in atrophy of epithelial elements and the recognizable epididymis becomes hard and nodular, perhaps enclosing dilated remnants of epididymal duct (Fig. 5.32). Distinct hard "sperm stones," the end products of spermiostasis, may be present within such ducts. Concurrent testicular atrophy will also result in the epididymis appearing disproportionately large in relation to the testis.

Histologically, affected epididymal ducts contain fibrin, neutrophils, and spermatozoa in various stages of disintegration, damaged epithelium, macrophages, and multinucleate giant cells, many of which contain spermatozoa. Other features of sperm granuloma, with prominent interstitial accumulation of lymphocytes and plasma cells, become apparent (Fig. 5.33). Epithelial hyperplasia, with the development of intra-epithelial lumina has been observed in most domestic species in association with epididymitis, but such lumina also occur in noninflammatory lesions. In chronic epididymitis, squamous metaplasia of epithelium may also occur in affected ducts in association with progressive fibrosis, and there may be hypertrophy of smooth muscle surrounding ducts.

Epididymitis may also be caused by sperm granulomas resulting from congenital ductal anomalies, adenomyosis, trauma, and infections.

Epididymitis in bulls

Infectious and immunologic causes of epididymitis in bulls are largely the same as those for orchitis, but bulls develop a specific infectious epididymitis, so-called epididymitis-vaginitis ("epivag"), first described in Kenya and later in South Africa. Lesions in the bull consist of initial soft swelling of the epididymis with subsequent enlargement and fibrosis. Associated lesions are "abscess" formation, tunic adhesions, ampullitis and vesicular adenitis, and testicular degeneration. Sometimes, however, the vesicular glands only are

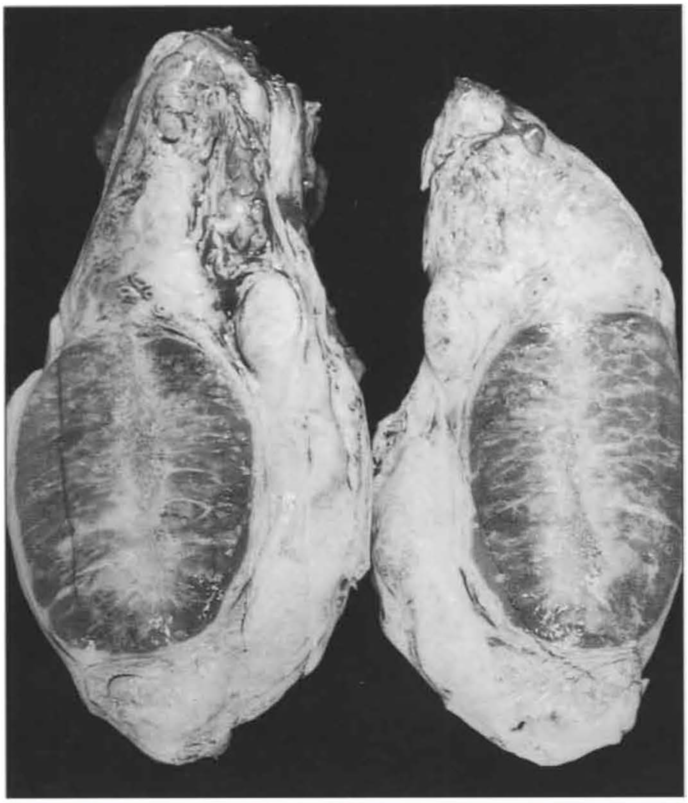

Figure 5.32 Chronic epididymitis in a bull, with marked epididymal fibrosis, adhesion of the tunica vaginalis, and marked testicular atrophy.

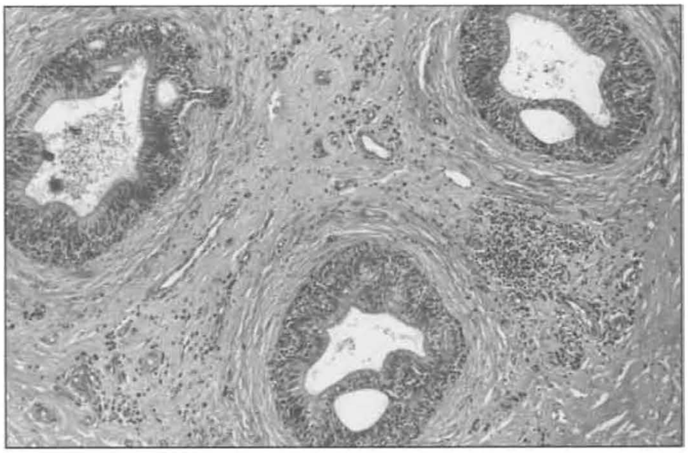

Figure 5.33 Chronic epididymitis in a ram, with interstitial fibrosis and epididymal epithelial hyperplasia and intraepithelial lumina formation.

affected. The possible role of a herpesvirus in the pathogenesis of "epivag" is discussed in Vol. 3, Female genital system.

Brucella abortus rarely causes epididymitis in the absence of orchitis. *Actinobacillus seminis*, a frequent cause of epididymitis in rams, has been isolated from the semen of a bull with bilateral epididymitis. Epididymitis has been observed in bulls with vesicular adenitis induced by inoculation of *Mycoplasma bovigenitalium*, but the roles of mycoplasmas and chlamydias in causing epididymitis await clarification. Epididymitis may accompany orchitis, periorchitis, and testicular degeneration in cattle, sheep, goats, horses, and dogs infected with *Trypanosoma brucei*.

Epididymitis in small ruminants

Epididymitis is of particular importance in rams, in which it is a frequent and serious cause of reduced fertility. Although one of two organisms *Brucella ovis* or *Actinobacillus seminis* are usually associated with the condition, many other bacteria, such as *Histophilus somni*, *Mannheimia haemolytica*, *Escherichia coli*, and *Arcanobacterium pyogenes* have been isolated from cases of epididymitis. Whereas *Brucella ovis* is a cause of epididymitis in mature rams, other gram-negative pleomorphic organisms are found more commonly in epididymitis in virgin rams, suggesting the existence of two separate disease entities, dependent upon sexual experience of the animal.

Ovine epididymitis caused by *Brucella ovis* is an important cause of reduced fertility in many countries and has been extensively studied. Progression of the disease is very slow, from a local infection persisting in the exposed mucous surface for 1 month, to a regional one involving adjacent lymph nodes, leading to bacteremia. The bacteremic stage appears to subside after about 2 months, but organisms localize in the genital tract, spleen, kidney, and liver where they persist for an indefinite period. Following experimental infection, neither gross nor microscopic lesions are seen in organs other than genitalia.

In approximately 90% of epididymides with lesions caused by *Brucella ovis*, the epididymal tail is involved, and lesions in this location probably occur in all epididymides infected with this organism. Initial localization of the bacteria produces edema, and lymphocytic and macrophage infiltration. Later, neutrophils are added when spermatozoa enter the interstitium. Early epithelial changes include hyperplasia and hydropic degeneration, with the formation of intraepithelial lumina (Fig. 5.33). At the same time there is increasing fibrosis in interstitial areas. The combination of fibrosis and epithelial hyperplasia obstructs the lumen and causes spermiostasis. These changes develop over many months, and large numbers of organisms are excreted in the ejaculate. Subsequent events depend on the extravasation of spermatozoa and formation of sperm granulomas. The tail of the epididymis in these cases may be enlarged 4–5 times (Fig. 5.34), and the lesion is often bilateral. If the extravasated spermatozoa enter the cavity of the tunica vaginalis, adhesions will result and testicular degeneration increases. Unlike brucellosis in the bull, there is no primary orchitis. Lesions in the deferent duct similar to those in the epididymis may occur, but are not associated with sperm stasis or leakage. There is pronounced epithelial hyperplasia, with thickening and folding of the wall, and the lamina propria is densely infiltrated with lymphocytes, plasma cells, and histiocytes. Unfortunately for control purposes, many rams do not develop detectable gross lesions or they develop them only late in the course of the disease. Identification of *B. ovis* in histological sections is difficult, but can be aided by immunohistochemistry.

Actinobacillus seminis and related strains of the so-called gram-negative pleomorphic organisms also induce epididymitis (Fig. 5.35). These bacteria consist principally of *Histophilus somni* (*Histophilus ovis*) and *Actinobacillus seminis*. Both *H. somni* and *A. seminis* are temporarily resident in the prepuce and become opportunistic pathogens by ascending infection, under appropriate conditions, such as those resulting at puberty from elevated levels of LH and FSH releasing hormones. The pathogenesis of *E. coli* epididymitis in rams probably is similar. Typically, these are acute infections that occur mostly in young rams, and there may be severe and diffuse periorchitis. In epididymitis caused by *Actinobacillus seminis*, there is abscessation of one

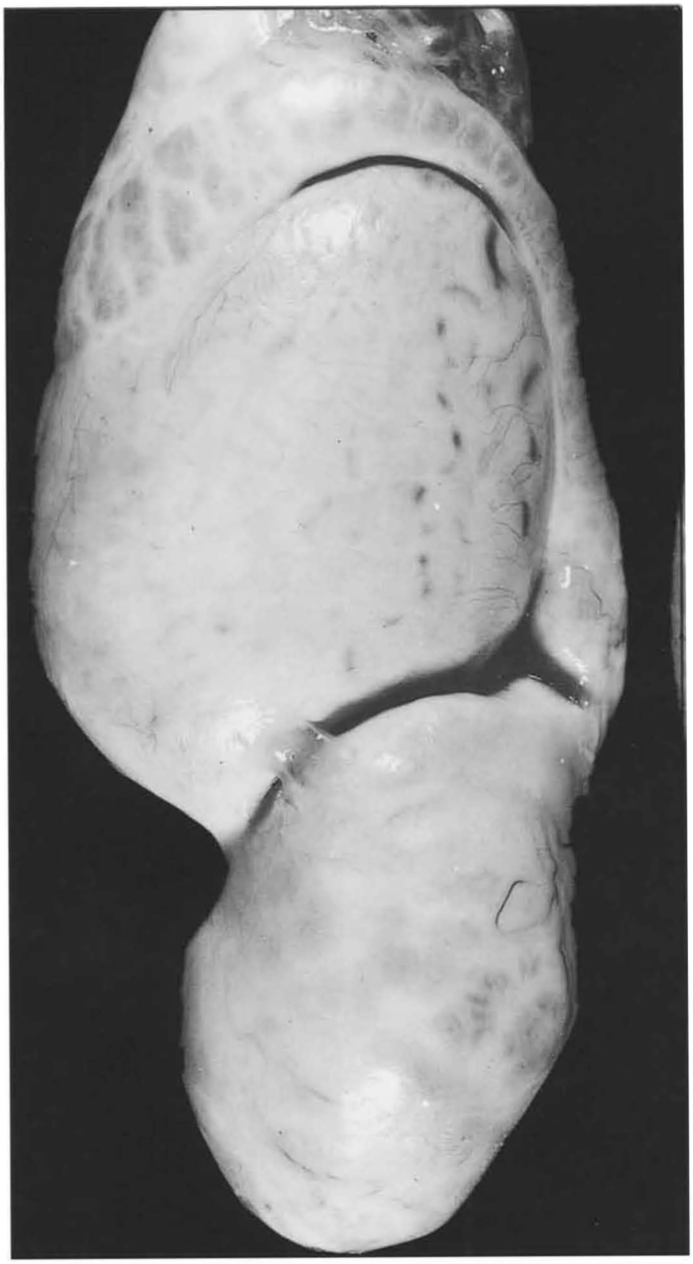

Figure 5.34 Chronic epididymitis in a ram, caused by *Brucella ovis*. The epididymal tail is enlarged with fibrosis and sperm granulomas (not visible). The testis is also atrophic.

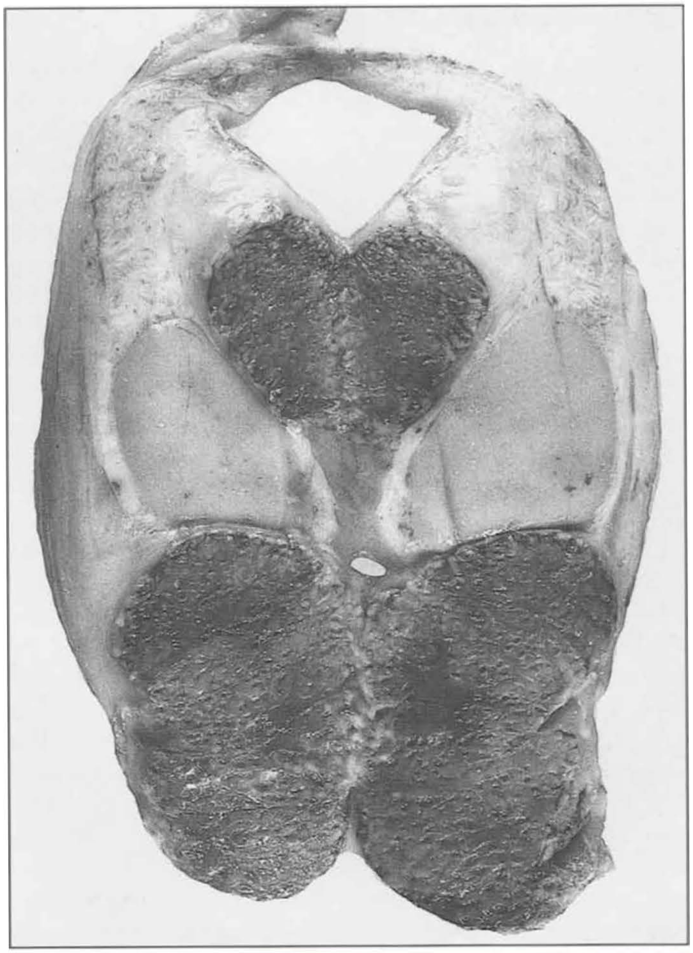

Figure 5.35 Acute epididymitis caused by *Actinobacillus seminis* in a ram. (Courtesy of KL Hughes.)

or both epididymides, and these may fistulate through the scrotal wall. Histologically, the initial epididymal lesion is similar to that of *Brucella ovis*, being characterized by intraepithelial lumina. In the chronic form of the disease seen in older rams, the epididymides are enlarged and fibrotic, and the testes are atrophic. The vesicular glands or prostate also may be affected. Experimental inoculation of rams by various routes with *Actinobacillus seminis* has shown that part of or the entire genital tract may become infected, but that the epididymis is most constantly involved.

Lesions in the epididymis caused by *Histophilus somni* are similar. The disease occurs sporadically, is sometimes accompanied by a febrile response, and the most frequent lesion is a large multilobulated abscess affecting one epididymis. The abscess cavities contain much fluid and green-yellow flocculent material, often with lumps of necrotic material. Fibrous adhesions of the tunics also occur. In early cases with epididymal abscessation, the deferent duct is usually patent and contains pus and spermatic fluid but in older cases that part of the epididymis adjacent to the deferent duct is usually empty and has grossly fibrosed walls. Microscopically, the early response is severe suppurative inflammation involving the walls of epididymal tubule. In appropriately stained sections, numerous bacteria can be demonstrated in intraluminal necrotic debris. Subsequently, infection may extend to the stroma, so that in chronic cases there is extensive interstitial epididymitis with much fibrosis. As with brucellosis, the testis is only involved secondarily.

Epididymitis is less studied in **bucks** than in rams. *Brucella melitensis*, *Actinobacillus seminis, Staphylococcus aureus*, *Escherichia coli*, or *Pseudomonas* spp. may be isolated from lesions, and there is a report of possible *Brucella ovis* epididymitis in an angora goat.

Epididymitis in boars

In boars, the macroscopic lesions caused by *Brucella suis* infection are quite variable. Single or multiple "abscesses" are frequent in the epididymis, but less so in the testes, which may be enlarged or atrophic. Enlargement of the vesicular glands due to localization of *B. suis* may also occur, and abscessation, perhaps seen only microscopically, occurs in the vesicular glands and prostate and bulbourethral glands.

Epididymitis in dogs and cats

In male dogs infected with *Brucella canis,* there is epididymitis, prostatitis, scrotal dermatitis, and testicular atrophy. These changes can be unilateral. Infected animals are bacteremic and the organism can persist in certain tissues, particularly the prostate, for many months, but recovery can eventually occur and recovered dogs are immune to reinfection. Venereal transmission to females by infected males can occur, although the organism is not consistently isolated from semen. Scrotal swelling is apparent 1–2 weeks after experimental intravenous inoculation, or 3–5 weeks after oral infection. Such swelling is caused by accumulation of fibrinopurulent exudate in the cavity of the tunica vaginalis. Scrotal ulceration is the result of persistent licking of the scrotum caused by the pain of epididymitis. Testicular abscesses are seldom if ever observed but testicular necrosis (as observed in the bull) may occur rarely, and is accompanied by marked fibrous thickening of tunics.

Microscopically in such cases, there is coagulative necrosis with a predominantly mononuclear, reparative response in peripheral areas where necrotizing vasculitis and associated thrombosis may also occur. More frequently, however, histological findings are those of interstitial epididymitis and prostatitis, and testicular atrophy. Lymphocytic infiltration of epididymal stroma is variable. Fibrosis may be extensive but, in contrast to brucellosis in other species, obliteration or stricture of ducts is unusual. Lymphocytes, neutrophils, and macrophages are present in the epididymal duct. In chronic cases, there is marked enlargement of the epididymis, especially the tail, with possible spread of inflammation to the deferent duct. As well as containing inflammatory cells and an increased percentage of abnormal spermatozoa, the ejaculate of male dogs with chronic brucellosis contains spermatozoa agglutinins, and the resulting infertility may, in part, be mediated by isoimmune reactions resulting from the heightened nonspecific phagocytic activity of inflammatory cells attracted to the sites of bacterial growth in the epididymis. *Brucella suis* also may cause spontaneous granulomatous epididymitis and prostatitis in the dog.

Escherichia coli or other gram-negative bacteria cause most sporadic cases of canine epididymitis (Fig. 5.36). The epididymitis caused by these agents is often seen as an acute disease and the dogs may be systemically ill with endotoxemia. Scrotal swelling and mutilation is relatively common. Following infection of dogs with *Burkholderia pseudomallei*, epididymitis, orchitis, and scrotal edema may occur in association with pyrexia, depression, swelling of one or more limbs, and lameness. Macroscopically, the epididymides are enlarged to perhaps 3–4 times normal size, are firm and hemorrhagic, and may contain small abscesses or necrotic foci. The testis and deferent duct may also be involved.

Mycoplasma canis can cause urinary tract infection in dogs, with subsequent purulent epididymitis and prostatitis.

Mycotic epididymitis caused by *Rhodotorula glutinis* or *Blastomyces dermatitidis* produces granulomatous epididymitis with a reaction pattern similar to disease in other tissues. The complication of sperm granulomas adds to the granulomatous nature of the disease.

Epididymitis occurs in sexually mature dogs with *canine distemper.* The histological appearance is similar to that seen in epididymitis of other causes, but, in addition, cytoplasmic and intranuclear inclusions are present in the epithelial cells. Some care is necessary to differentiate the specific inclusions from the eosinophilic cytoplasmic bodies normally present in the head of the epididymis and from the intranuclear bodies that are present in normal dogs; immunohistochemistry will differentiate inclusions in question.

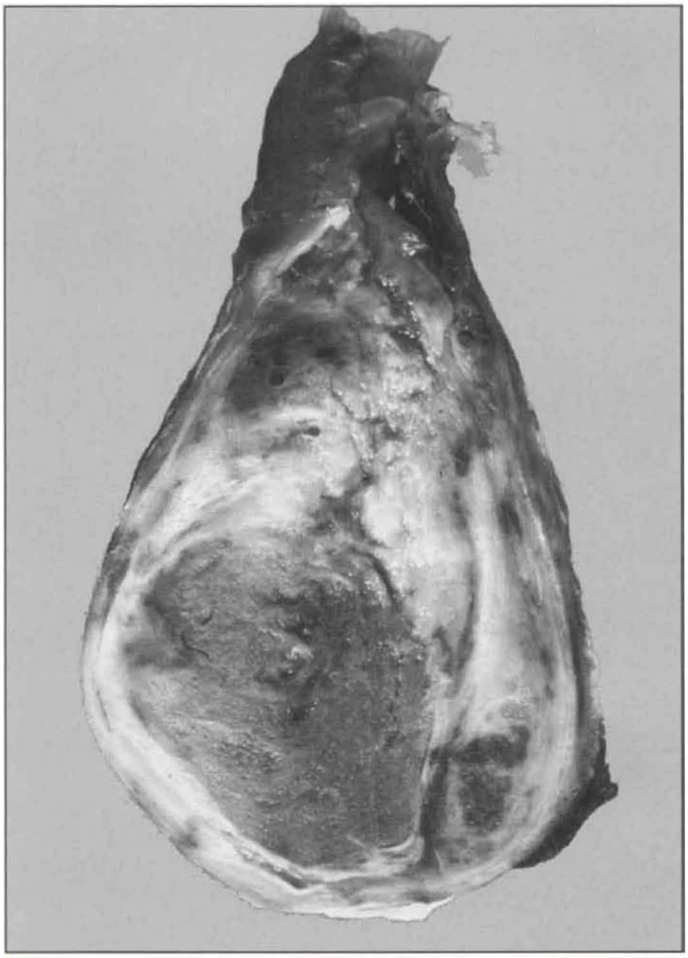

Figure 5.36 Severe **epididymitis and periorchitis** in a dog. The tail of the epididymis is large and edematous, and there is fibrin and exudate in the cavity of the tunica vaginalis.

Epididymitis is exceedingly rare in **cats**. It has been seen as fibrinonecrotic vasculitis and epididymitis in association with genital involvement in feline infectious peritonitis. Ascending epididymitis also occurs.

Epididymitis in stallions

In the stallion, migrating strongyle larvae are considered a likely cause of epididymitis and sperm granuloma of the epididymis; adenomyosis has been shown to be a further cause. Rare sporadic cases of bacterial epididymitis are also reported. *Streptococcus zooepidemicus* has been isolated from such cases.

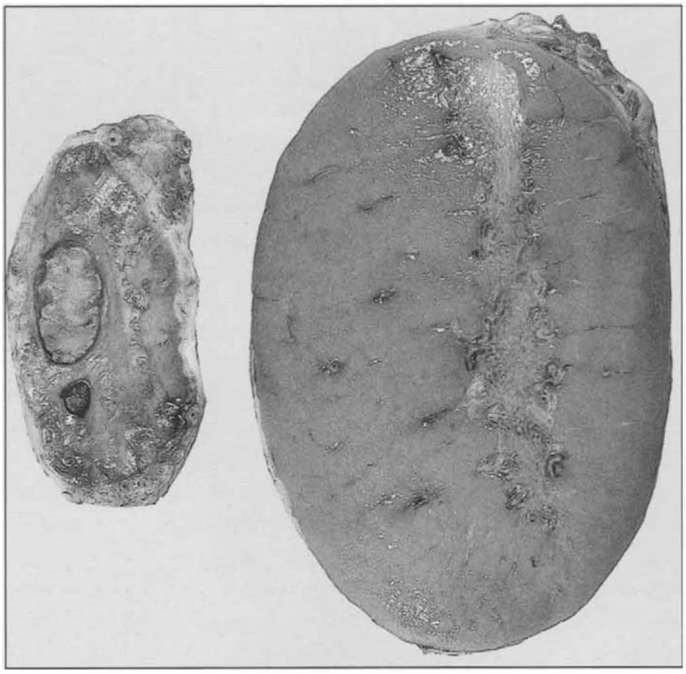

Figure 5.37 Atrophy and infarction of the left testis of a bull due to compression of the spermatic cord while removing tissue for biopsy. The right testis is normal.

Circulatory disturbances

The spermatic artery is very long because of the coiled portions proximal to the testis. The degree of coiling varies between species, being quite pronounced in ungulates, in which the spermatic artery is several meters long. Testicular blood flow is low in relation to metabolic needs, and hypoxia develops quickly if increasing testicular temperature increases metabolic demand or if blood flow is impaired. By the time the artery penetrates the tunica albuginea, pulsatile flow is almost eliminated and the structure of the vessel changes. The diameter enlarges, the wall becomes thinner, and the elastic fibers are reduced. Increased intratesticular pressure will have dramatic effects on circulation.

The interstitial tissue of the testis is richly supplied with *lymphatics*. In addition to the usual role in fluid exchange, they probably assist in transportation of hormones between interstitial endocrine cells and the tubules. Edema of the testis occurs after trauma and is a frequent early change in orchitis. Although the tunica albuginea is relatively indistensible, some enlargement can occur and serous fluid drips from the cut surface. There is distinct separation and dilation of tubules, diffuse vacuolation of germinal epithelium, and dilation of lymphatics.

Hyaline degeneration of the walls of arterioles is associated with wedge-shaped areas of fibrosis in the testes of old bulls, but the precise cause of this lesion is not clear. In old dogs, hyaline degeneration of both arterioles and arteries accompanies testicular degeneration. Initial lesions occur in the tunic and parenchyma, but larger vessels in the spermatic cord are subsequently involved. Focal areas of infarction may occur as a result of severe vascular lesions. Atheromatous lesions are rare; in dogs they may indicate hypothyroidism or diabetes mellitus.

Thrombosis of testicular arteries, usually of unknown cause, is seen occasionally in bulls. Such thrombi are present in both the parenchyma and tunics and may be partially mineralized and sometimes occluding. The mild degenerative changes in germinal epithelium in association with thrombi emphasize the good collateral circulation. In experimental *Trypanosoma vivax* infection in sheep, thrombosis of testicular vessels probably contributes to testicular degeneration. Subsequent infarction and necrosis may sometimes occur. Occluding venous thrombosis has been observed in the testes of rams. Some had a concurrent varicocele; testicular degeneration associated with such thrombi was mild.

Inflammation of the testicular artery occurs frequently in the horse. The known causes are migrating strongyle larvae and *Equine arteritis virus*, but the cause is not established in many cases. The usual morphologic manifestations in testicular tissue include focal infiltration of lymphocytes and degeneration of seminiferous tubules adjacent to the inflamed arteries and arterioles. The inflammatory reaction is rarely of such a severe degree as to cause thrombosis and infarction. Horses infected with *Equine arteritis virus* may have an acute lesion with a necrotic vasculitis, edema, and hemorrhage. Chronic cases will have lymphocytic vasculitis and perivasculitis.

A striking *vasculitis* with marked interstitial epididymitis, orchitis, and testicular degeneration occurs in malignant catarrhal fever in buffaloes and bulls in association with generalized vasculitis. Dogs may develop vasculitis as part of a localized or generalized polyarteritis, and it may occur in systemic necrotizing vasculitis ("Beagle pain syndrome").

Occlusion of the testicular artery with resulting ischemia of the testis may result from torsion, contusion of the spermatic cord, inappropriate placement and/or hypotension during surgery, or the use of an emasculatome for castrating young lambs and calves (Fig. 5.37). Experimentally, destruction of germinal epithelium can be demonstrated after ischemia of more than 1 hour. Necrosis of testicular parenchyma follows after 4–6 hours, although spermatozoa are relatively resistant to lysis and may retain their staining characteristics for weeks or months. Following ligation of the spermatic artery in prepubertal rams, however, revascularization of the tunica albuginea occurs by penetration of capillaries from the epididymal arteries. Islets of seminiferous tubules associated with the tunic (Moskoff's islets) may thus survive, and considerable regeneration occurs during the ensuing months. As the regenerated tubules lack a normal drainage system, there is spermiostasis and ultimately degeneration.

Torsion *of the testis is rare unless there is incomplete descent.* The stallion appears to be the exception, as spontaneous torsion is a recognized cause of "colic." In dogs especially, testicular neoplasia is often also present, to provide sufficient weight to maintain the torsion. The usual clinical presentation is acute abdominal pain, and the testis is blackened due to venous infarction, and is sometimes unidentifiable as testis. Spontaneous torsion of the cryptorchid testis of boars is seen commonly at slaughter. Torsion with complete ischemia and infarction will cause complete loss of spermatogenesis of the affected testis. Correction of torsion in laboratory animals and humans can save the testis, but some continue to be aspermatogenic even if infarction does not occur. Interstitial endocrine cells and Sertoli cells retain their ability to function, but reactive oxygen species may induce germ cell apoptosis and loss.

Neoplasms of the testis and epididymis

Testicular neoplasms are most commonly found in the dog. There is no satisfactory explanation for this, but intact dogs are allowed to live as long as they are able, and they tend to be watched closely. Male cats tend to be castrated early and fewer of those that are intact live to old age. Neoplasms arise in all species sporadically, and with the exception of the dog, it is possible to predict the histologic type of neoplasm based on species and age. Seminoma is the common tumor of the aged horse, and teratoma is more common in the young. Cats, boars, rams, and bucks rarely get testicular neoplasms, and both seminoma and Sertoli cell tumor are reported. Bulls are more likely to have interstitial cell tumors, but Sertoli cell tumors are also reported.

The three main testicular neoplasms of dogs are the Sertoli cell tumor, the interstitial (endocrine) cell tumor, and the seminoma. The fourth most common, but still rare, is a mixed germ cell and stromal cell neoplasm. Multiple types of neoplasia may be found in one testis. *Most primary testicular neoplasms in dogs are benign.* Exceptions are rare, but malignant Sertoli cell tumors and seminomas are reported. Identification of metastasis in lymphatics, spermatic cord, lymph node, or distant sites is the only way to determine that the neoplasm is malignant; there are no good cytological or histologic markers of malignancy.

Most neoplasms cause enlargement of the testis. In general, seminomas are white, soft, and usually bulge on cut section. Sertoli cell tumors induce fibrous tissue so they are white and are tough. The interstitial cell tumor is yellow, often contains areas of hemorrhage, and is soft. *Sertoli cell tumors, and rarely interstitial cell tumors, may produce a hyperestrogenism syndrome and feminization.* In dogs, this is usually manifested by attractiveness to other male dogs, gynecomastia, and alopecia. Prostatomegaly and squamous metaplasia of the prostate also occur. Affected animals return to normal after removal of the neoplasm. The signs are not always associated with estrogen production and not all dogs will have a raised serum estrogen concentration. In these instances, inhibin secretion by the neoplastic Sertoli cells inhibits the secretion of FSH and LH by the pituitary, which, in turn, inhibits testosterone production and presumably alters the ratio of estrogen to testosterone. Some animals will develop bone marrow suppression, and poorly responsive pancytopenia. Feminization is much more common when the neoplasm is larger, and therefore is more common in cryptorchid dogs. It is also in these dogs that the unfortunate sequel of testicular torsion can occur.

Testicular tumors are seen mostly in mature and old animals; the occurrence of interstitial cell tumors in dogs is especially age associated. Canine testicular tumors are found more frequently in the right than in the left testis, and this is also true for the cryptorchid testis.

Other neoplasms of the testis include the *mixed germ cell–sex cord–stromal neoplasms* that have been reported in the horse and dog, *rete adenoma and adenocarcinoma*, and *embryonal carcinoma* in the horse.

Metastasis of neoplasms to the testis is rare. Lymphoma in the horse, dog, and bull, and hemangiosarcoma in the boar and dog are reported. The list will no doubt increase in length if pathologists routinely examine the testes at all necropsies.

Epididymal neoplasms are exceedingly rare. Ectopic interstitial cell tumors have been described in the cat. Lymphoma or any other systemically metastatic neoplasm may affect the testis and epididymis.

Gonadal stromal tumors

Interstitial (Leydig) cell tumor

Interstitial cell tumors are derived from the endocrine cells of the testicular interstitium. They are grouped with Sertoli cell tumors in being derived from tissue of the sex cords or stroma. Lesions that are less than 1 cm in diameter may be hyperplasia, although this distinction may have little biologic significance.

In the dog, interstitial cell tumors are found chiefly in older animals. It also occurs in the bovine testis, is found in the older age groups, and mainly in Guernseys. In horses, the tumor develops almost exclusively in cryptorchid testis. There are very few reports of testicular neoplasia in boars, but interstitial endocrine cell hyperplasia and tumor are more common than the others.

Normal interstitial endocrine cells produce androgens, and some interstitial cell tumors of dogs have been shown to produce excess androgen, but *most tumors do not cause signs of hyperandrogenism.* Signs of hyperestrogenism have been observed in a few dogs with interstitial cell tumors and estradiol concentration in testicular venous blood of affected dogs may be elevated. The condition has been corrected by removal of the neoplasm. However, in dogs,

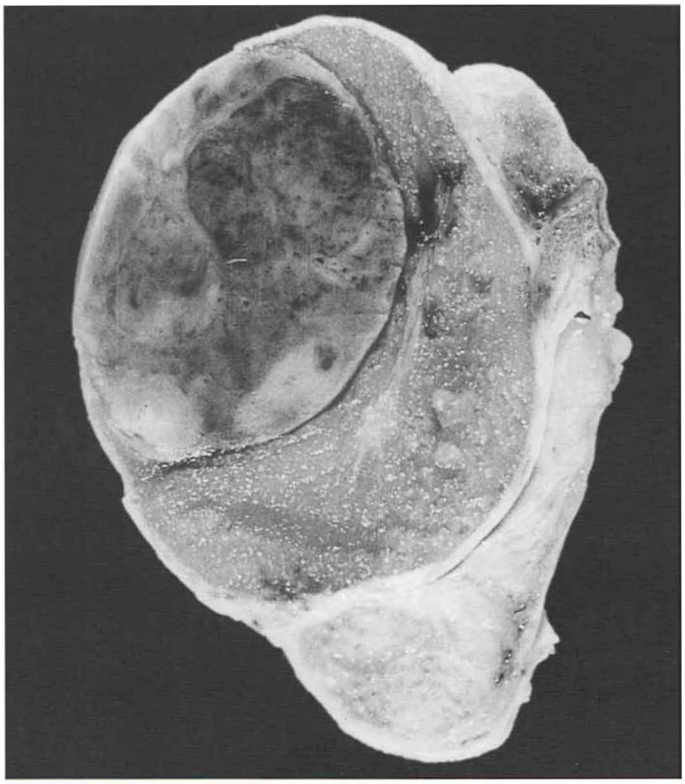

Figure 5.38 Intratesticular **interstitial cell tumor** in a dog. These are soft and tan, with regions of hemorrhage.

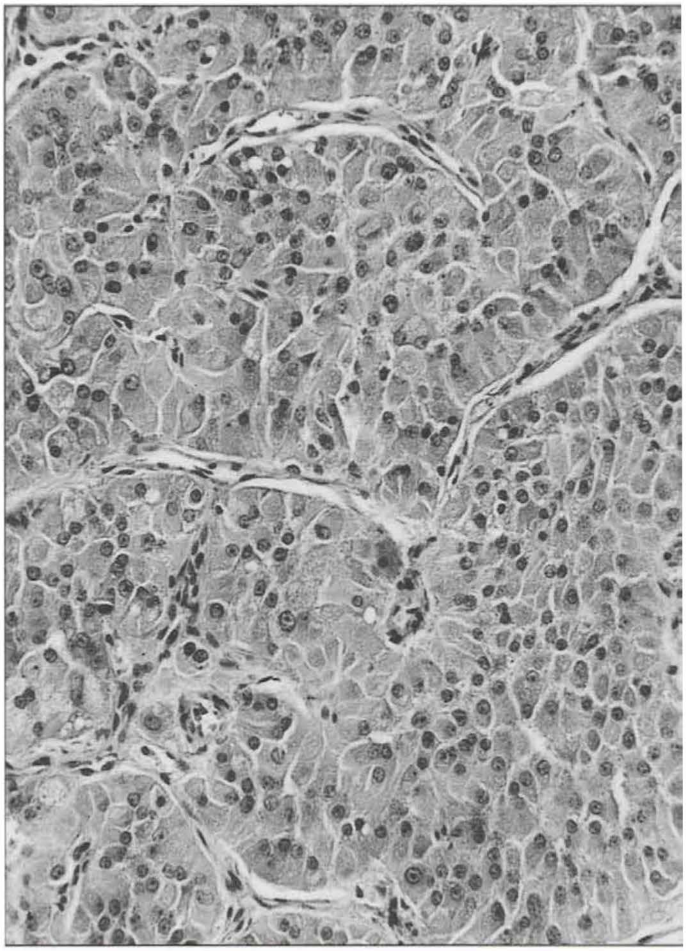

Figure 5.39 Endocrine pattern, with large polygonal cells packed into groups by a fine fibrous stroma, of an **interstitial cell tumor** in a dog.

a common association is with perianal gland neoplasia, tail gland hyperplasia, and prostatic enlargement, which suggests that secretion of excess androgens also occurs.

Interstitial cell tumors in stallions have been seen most often in undescended testes. They contain two cell types; the first is essentially a hypertrophic interstitial endocrine cell but the other is a pleomorphic fusiform cell with fibrillar, vacuolated cytoplasm and indistinct borders. Hormone determinations have not been reported on horses with these tumors, but viciousness, which was corrected by castration, has been observed.

A high incidence of telangiectasis of the liver, thyroid C (parafollicular) cell tumors, and infertility has been observed in Guernsey bulls with interstitial cell tumors, but it is not known whether the lesions are in any way interdependent or possess a common denominator.

Nodular hyperplasia is probably a preneoplastic change in some instances of interstitial cell tumor of the dog. The hyperplastic nodules occur principally in testes that have undergone senile atrophy and, although they may be macroscopically visible, the nodules are small, nonencapsulated, and consist of an increased number of interstitial endocrine cells in the intertubular stroma. The apparent diffuse hyperplasia of interstitial endocrine cells in cryptorchid and hypoplastic testes does not predispose to the development of tumors. In both nodular and diffuse hyperplasia, the hyperplastic cells are regular in form and size with increased acidophilia of the cytoplasm and without mitoses.

Interstitial cell tumors in the dog are often multiple, but may be solitary and unilateral or bilateral (Fig. 5.38). Commonly they are from 1 mm to 2 cm or more; only exceptionally are they large enough to increase the size of the organ, but they may lend the organ an irregularity in contour, the rounded bulge of the tumor being visible in an otherwise small, soft, atrophic testis. On cut surface, the tumors are well demarcated but only lightly encapsulated, spheroidal, and yellow. The tumor is predisposed to hemorrhage which causes dark discoloration, and to cyst formation in areas. Even a large tumor may be obviously composed of confluent nodules indicating multicentricity of origin, and this is readily apparent in the form of discrete tumors when they are small. The consistency is soft, there being little stroma, and the cut surface is slightly greasy.

Interstitial cell tumors grow slowly and expansively with surrounding compression atrophy, and often with a thin condensed capsule. They are not notably invasive. In bulls with interstitial cell tumors, semen production and fertility may be reduced.

Typically, the component cells in the dog are rather respectable interstitial endocrine cells, being round or polyhedral, with abundant cytoplasm that may be granular or vacuolar and that often contains yellow lipochrome pigment (Fig. 5.39). The neoplastic cells in the bull are not vacuolated and contain very little lipid. Sometimes and in some tumors, the cells have a more mesenchymal appearance, being spindle-shaped with indistinct cytoplasmic outline and a streaming arrangement. It is in such tumors especially that necrosis and cyst formation occur. The nuclei are regular in size and staining affinity, and mitoses are rare. The stroma is scant, supporting a capillary network, but occasionally suffices to give the tumor an endocrine appearance.

Intranuclear cytoplasmic invaginations or inclusions have been observed consistently in up to 15% of neoplastic cells in canine interstitial cell tumors. The inclusions, which are strongly PAS-positive and which are composed of smooth and rough endoplasmic reticulum, vesicles and lipid vacuoles, myelin figures, and disrupted membranous profiles, have not been demonstrated in other testicular tumors. Nuclei containing these invaginations are enlarged. Except where invaginations are present, the ultrastructural appearances of neoplastic and normal interstitial endocrine cells in the dog are similar.

Sertoli cell tumor

The Sertoli cell tumor is rare in domestic species other than the dog, but has been observed in the bull, horse, ram, and cat. These tumors often cause enlargement of the affected testis, and there is, sometimes, the development of a *feminization syndrome* in the host. The feminizing effect of these tumors is due to either their high content of estrogen or to secretion of inhibin. The degree of differentiation of the neoplastic cells will influence the content of hormone but, usually, it is larger tumors that are responsible for feminizing syndromes, which suggests that the mass of the tumor is related to the quantity of hormone elaborated. The attractiveness of affected dogs to other male dogs is well known, but a hyperestrogenism syndrome also is manifest as reduction of libido, female distribution of body fat, cutaneous and pilosebaceous atrophy leading to symmetrical alopecia, atrophy of testes and penis, an estrogenic form of mammary development, swelling of the prepuce, and hyperplasia or squamous metaplasia of the prostate, which may be accompanied by perineal hernia. Prostatic metaplasia can progress to the stage where quite large keratin accumulations fill glandular lumina. Enlargement of the seminal colliculus with partial obstruction of the urethral lumen may also accompany prostatic changes in these dogs.

As well as feminization, there may be *depression of bone marrow activity* with resultant clinical signs of hemorrhage caused by thrombocytopenia, anemia caused by blood loss and/or diminished erythrocyte production, and infection and fever associated with granulocytopenia. Recovery may follow castration and supportive therapy.

The gross appearance of a Sertoli cell tumor can be quite distinctive. The larger tumors are somewhat irregularly ovoid, lobulated and enclosed in a tense tunica albuginea (Fig. 5.40). The cut surface bulges and usually is white and quite firm or even hard, although sometimes it may be discolored or cystic. *The firmness of the tumor is due to the abundance of its stroma,* something the other two common types of tumor have in small amounts only.

Although metastasis of Sertoli cell tumor to the regional lymph node is unusual, local extension of neoplastic tissue into the testicular vein and associated lymphatics may result in hydrocele with massive swelling of the scrotum.

Histologically, Sertoli cell tumors may be of two types, either intratubular (with or without invasion as determined by penetration of the basement membrane) or diffuse. *There seems to be little correlation, however, between histologic type and metastasis.* Stroma is always plentiful, and it may be hyalinized. The stromal tissues are commonly arranged to provide a tubular pattern in which the neoplastic cells tend to palisade. Such arrangements to some degree can be found in most Sertoli cell tumors (Fig. 5.41A, B). In the early and well-differentiated tumors, the cells resemble normal Sertoli cells, being rather elongate with foamy acidophilic cytoplasm and small, basally situated, dark-staining nuclei. In less differentiated varieties, the cells are still elongate and possess eosinophilic cytoplasm, but the nuclei are elongate and pleomorphic and no longer basally located against the trabecular pole (Fig. 5.41A, B). In the less common form of the tumor, the cells show little or no tendency to palisade but are discrete and spherical with well-defined eosinophilic cytoplasm and some nuclear irregularity. Mitoses are sparse. Lipids are demonstrable in the neoplastic cells as large droplets and globules in more differentiated tumors and as fine droplets in the least differentiated tumors.

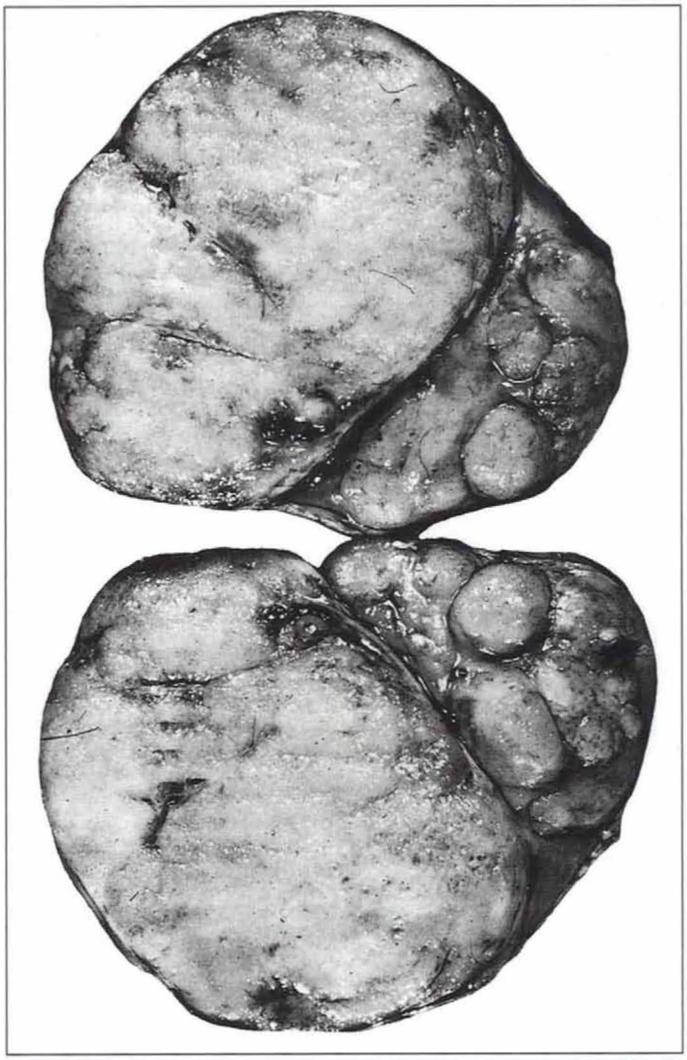

Figure 5.40 Malignant **Sertoli cell tumor** in a dog. Presence of metastasis is the only criterion to differentiate malignant from benign neoplasia.

Sertoli cells are reported to be the only cells of the testis that stain immunohistochemically with antibody to neuron-specific enolase, wherein the stain is intracytoplasmic. They stain diffusely intracytoplasmically with vimentin (as do interstitial endocrine cells). Cytokeratin stains are negative. There are varied reports of staining with other antibodies, including S100, melan A, and inhibin. Because of the conflicting results from different laboratories, it is not possible to generalize about their staining characteristics.

Ultrastructural examination of canine Sertoli cell tumors reveals that the characteristic specific intercellular junctions and crystals of

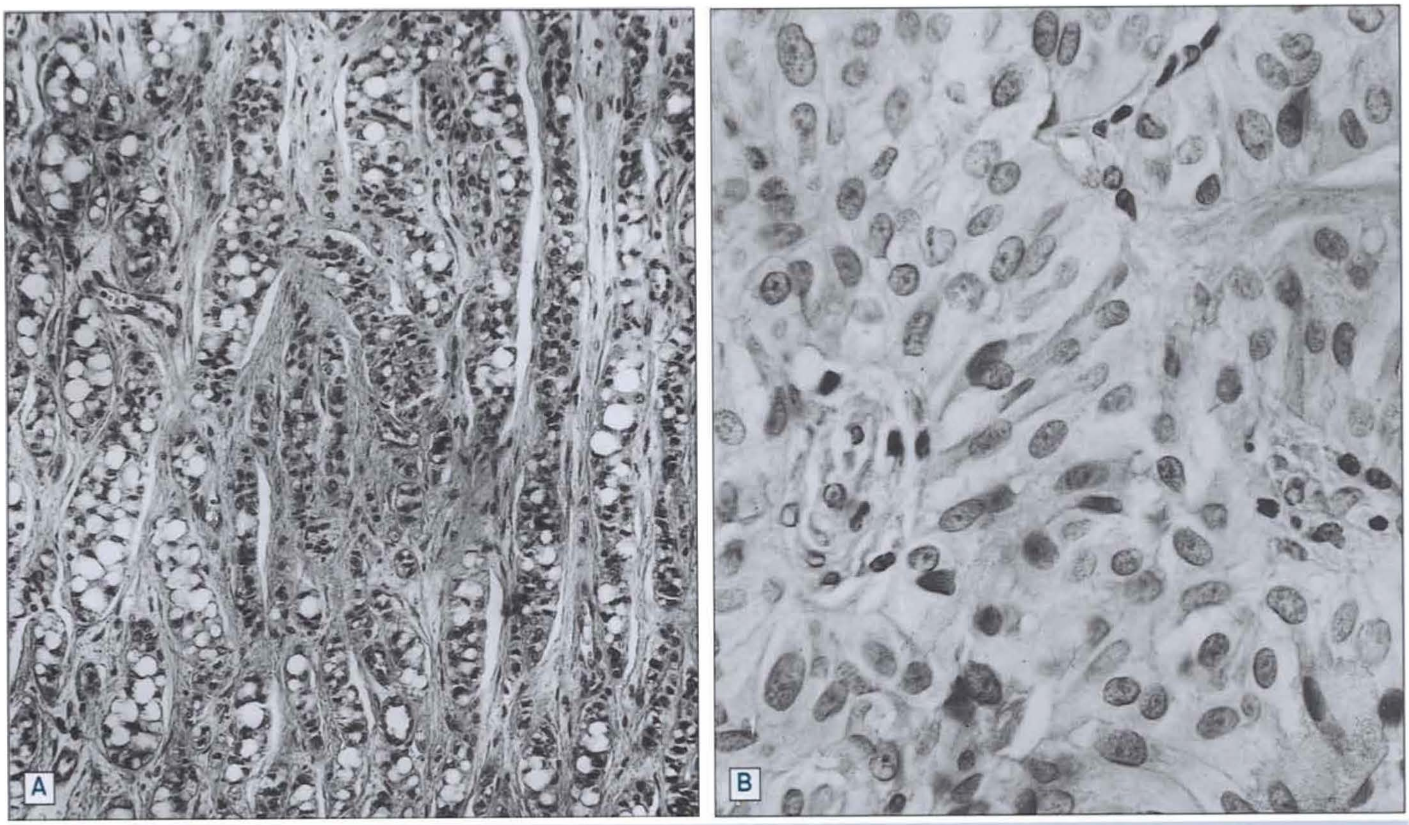

Figure 5.41 A. Histological appearance of **Sertoli cell tumor** in a dog showing tubular structures separated by abundant fibrous tissue. **B.** On higher magnification, the cells tend to bridge from one side of the tubular structure to the other.

Charcot–Bottcher do not occur in neoplastic cells. Nevertheless, a number of common features do persist so that these and the abundant intracytoplasmic organelles permit differentiation from interstitial cell tumors and seminomas. Prominent intercellular gap junctions have been observed in a Sertoli cell tumor in the dog and it is possible that these were induced by the hormonal activity of the tumor.

Early age of slaughter of most food animals precludes studies on true tumor occurrence with increasing age. However, in one study, in which **bulls** and buffaloes were kept until 9–14 years for draft purposes, 20 of 161 testes examined contained neoplasms; all but one were Sertoli cell tumors. Seven tumors were in undescended testes. In contrast to Sertoli cell tumors in the dog, those in cattle have been observed in newborn or young calves with sufficient frequency to suggest that impaired embryogenesis, possibly of genetic origin, might have some role in causation. In support of this suggestion is the presence, in some bovine Sertoli cell tumors, of laminated intratubular concretions resembling those seen in bovine testicular hypoplasia and cryptorchidism. Moreover the simultaneous occurrence of Sertoli cell tumor and epididymal aplasia has been observed. One described bovine Sertoli cell tumor was in a testis of an animal in which castration by the burdizzo method had been attempted 5 years previously. In general, the gross and microscopic appearance of Sertoli cell tumors in the bull resembles those in the dog (Fig. 5.42A, B). Metastasis of Sertoli cell tumor in the bull has not been observed, and there is no clear evidence of hyperestrogenism.

In **rams**, occasional Sertoli cell tumors, comparable to those in the bull, have been observed. Hyperplastic Sertoli cells occur in cryptorchid rams (Fig. 5.43), but whether these could potentially develop into neoplasms seems unlikely, given the rarity of the tumors.

One case of Sertoli cell tumor in a **stallion** involved the single descended testis; a ductal pattern of neoplastic Sertoli cells, which contained clusters of distinct hyaline bodies, was evident.

Germ cell tumors

Seminoma

Seminomas are common in canine testes and have also been observed in the stallion (and mule), ram, buck, and bull. They occur in *older animals* and are disproportionately common in cryptorchid testes. They arise from cells of the spermatogenic series, presumably from basal spermatogonia, and they are usually multifocal of origin in the affected testes. These tumors do not produce hormones. They are not often malignant, but are probably more so than either of the other two types. However, *they tend to be locally invasive* and there are no known factors to predict the metastatic potential of seminomas.

Seminomas often attain a size of 6 cm or more before removal, and by then the stretched tunica albuginea encloses neoplastic tissues only. Sudden enlargement of the testis, and pain caused by hemorrhage and necrosis in the tumor, are often the presenting signs in dogs. In all species, the sectional surface is coarsely lobulated by a few fine trabeculae, the color is usually white or gray-white, and the texture is soft to moderately firm (Fig. 5.44). If lightly squeezed, a milky fluid may exude from the cut surface. The texture and color closely resemble that of neoplastic lymphoid tissue.

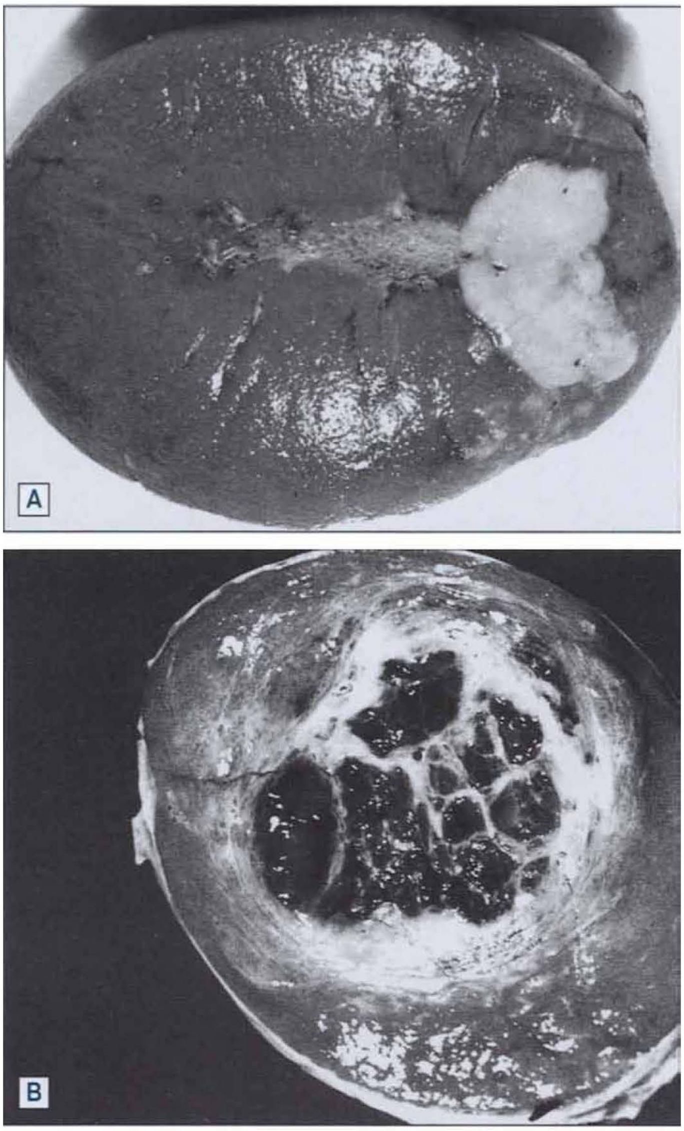

Figure 5.42 Sertoli cell tumor in a bull. Macroscopic appearance varies from (**A**) a solid to (**B**) a cystic type. (Both courtesy of J Comp Pathol.)

Microscopically, intratubular, and diffuse types are recognized. The earliest development of the tumor is intratubular and even in some large specimens intratubular growth is still evident and undoubtedly comprises one method of spread (Fig. 5.45A). Rupture of the tubules soon occurs and the growth becomes confluent, forming broad sheets of closely packed cells with scant supporting stroma. There is only slight cytological variation from tumor to tumor. The cells are large and polyhedral and fairly discrete, with a rim of visible cytoplasm that may be basophilic or eosinophilic (Fig. 5.45B). The nuclei are large and rounded and usually strongly chromatic with one or more large acidophilic nucleoli. In some tumors, the nuclei are larger and vesicular but still regular in shape, and the cells are closely packed with scant or invisible cytoplasm. In many seminomas, it is possible to find scattered mono- or multinucleate giant cells with abundant granular acidophilic cytoplasm. *Focal or diffuse accumulations of CD8+ lymphocytes occur in most seminomas and are a useful distinguishing feature.* Whereas atrophy of tubules at the edge of the tumor is normally evident, occasional foci of marked intratubular spermatogonial proliferation and early seminoma formation in this location are sometimes seen.

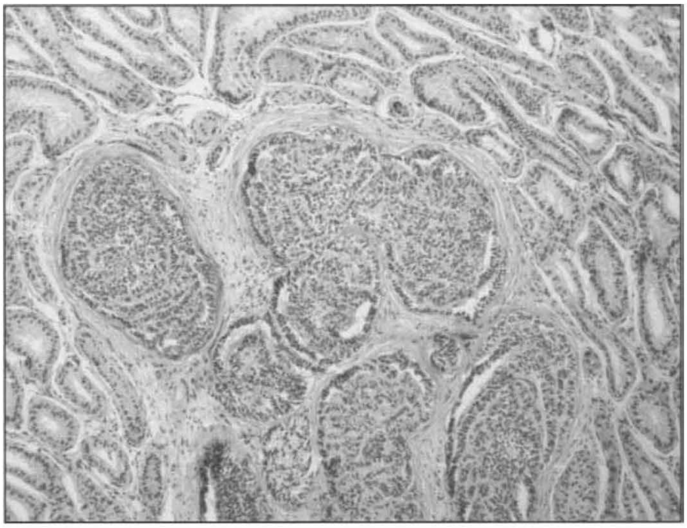

Figure 5.43 Focal **Sertoli cell hyperplasia** in the cryptorchid testis of a ram.

Germ cells stain by immunohistochemistry with *vimentin* in a perinuclear pattern, but they are negative for neuron-specific enolase and cytokeratin.

When examined by electron microscopy, tumor cells in canine seminoma resemble normal germinal epithelium and are characterized by a relative scarcity of cytoplasmic organelles, oval nuclei, straight cell borders, and distinct Golgi complex. Intercellular bridges, as seen in normal germinal cells, are present in seminomas. In all cases, the cells are markedly distinct from cells of interstitial or Sertoli cell tumors.

Presumably because abdominal location of seminomas in retained testes precludes their early clinical recognition, they may become quite large and metastasize widely. In the stallion, seminomas up to 9 kg have been found, and metastasis to most parts of the abdominal cavity and also the thoracic cavity, has been observed.

Intratubular seminomas have been reported in mature and aged rams with testicular degeneration. The proliferating spermatogonia are confined to the seminiferous tubules and do not attain sufficient size to be recognized on gross examination. It appears that this may be a dysplastic rather than a neoplastic process. A similar dysplastic process in otherwise degenerate testes is also observed in dogs. Several such foci occur in the organ, the affected tubules being slightly dilated and the abnormal cells distinctively large, rounded or polyhedral, usually multinucleate, and with pigments in the cytoplasm. Rarely, a highly malignant form of seminoma occurs in the ram, producing overall enlargement of the testis, and hemorrhage, necrosis, and massive neoplastic infiltration of the entire testis.

Seminomas are exceedingly rare in boars and cats.

Teratoma

Teratoma of the testis is a neoplasm that is virtually unknown in domesticated mammals other than the horse, in which it is the most frequently reported testicular tumor in the young animal. Equine teratoma is a benign tumor found in the scrotal, or more often, cryptorchid testis of young animals. It is probable that its presence in a fetal testis would prevent normal descent. There is a report of testicular teratoma that caused partial obstruction of the colon in a neonatal foal.

Macroscopically, teratomas are single or multiple and quite varied in color and texture. They are usually less than 10 cm in diameter

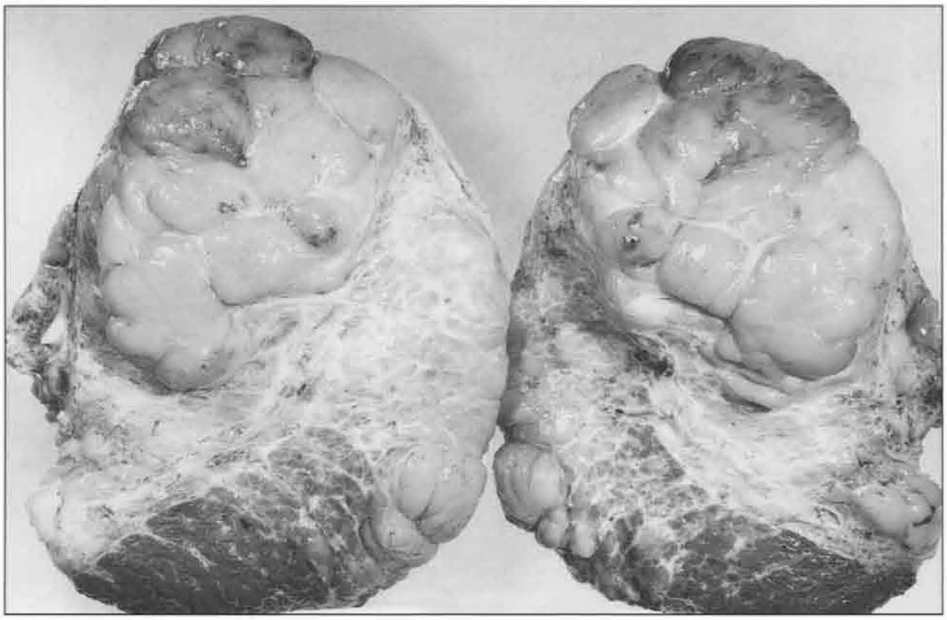

Figure 5.44 Multinodular appearance of a **seminoma** in a horse. The neoplastic tissue varies from white to tan, and can be firm. The adjacent testis is atrophic.

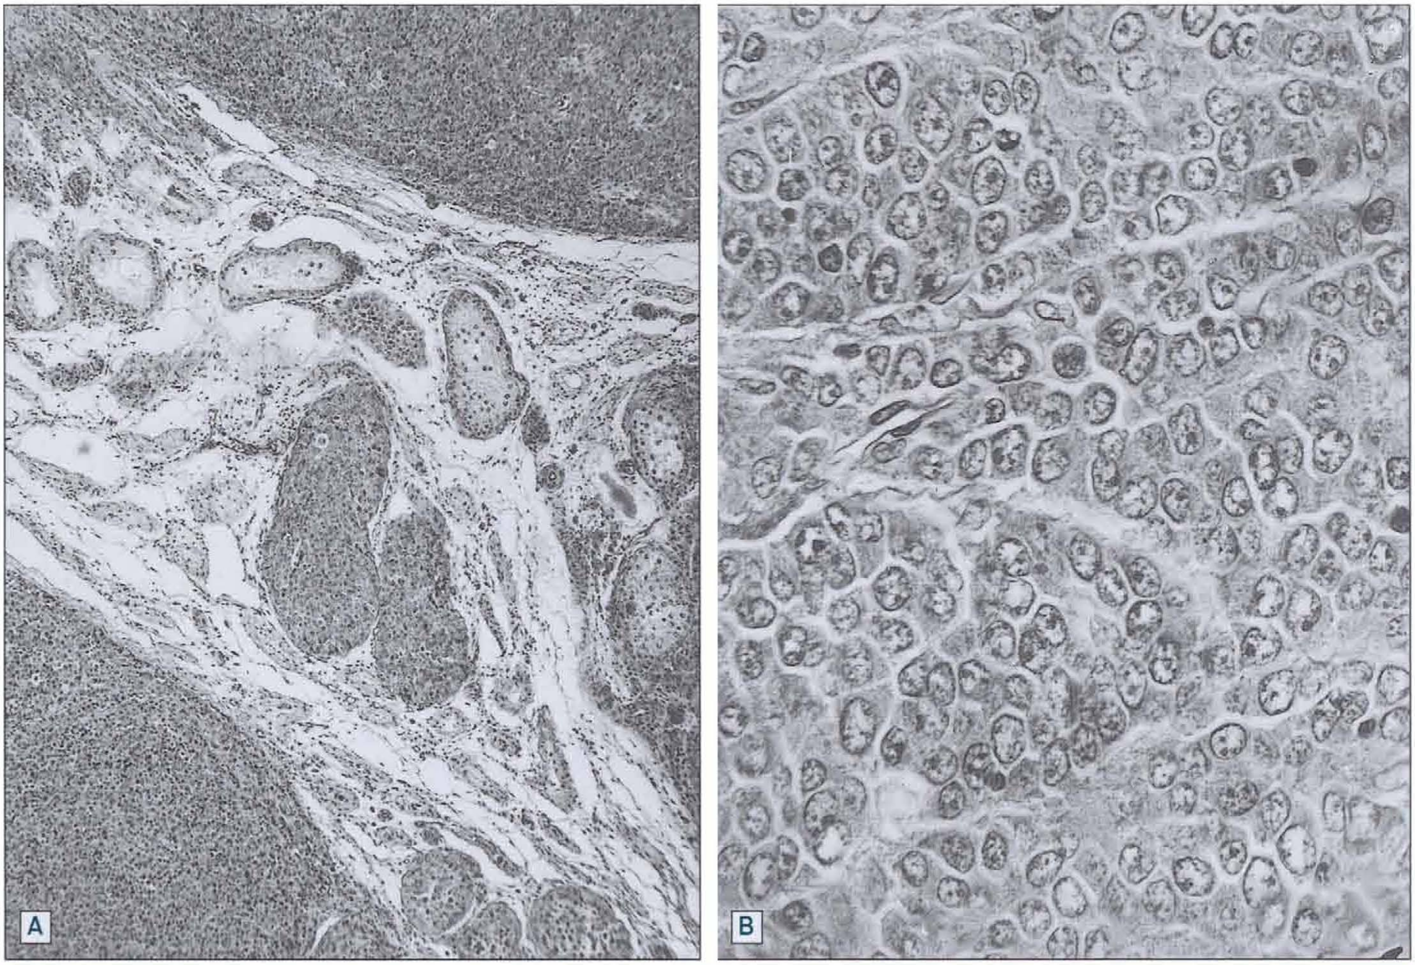

Figure 5.45 A. Seminomas usually have a combination of diffuse and intratubular growth. The adjacent testis may be atrophic as was the case in this horse. **B.** Histologically, the cells are large round cells with scant cytoplasm and large nuclei with prominent nucleoli. Mitoses are frequent.

but may be greater than 25 cm. A cystic and/or multilocular structure is common and, on section, hair and mucoid or sebaceous-like secretions are often seen, hence frequent use of the term "dermoid cyst." Yellow-white solid masses with fibrous, adipose, cartilaginous, and bony tissue are also frequent.

Histologically, *structures derived from all embryonic germ layers may be present*, including ectodermal (dermoid cysts, hair, teeth), neuroectodermal (nervous tissue, melanoblasts), entodermal (salivary gland, respiratory), or mesodermal (fibrous or adipose tissue, bone, muscle). Nervous tissue is almost always present, and adipose tissue is also very common. Testis adjacent to a teratoma may show reduced spermatogenesis, with various degrees of tubular atrophy. The histogenesis of gonadal teratoma is discussed in Vol. 3, Female genital system.

Embryonal carcinoma

Embryonal carcinoma is rare in animals but is of significant frequency among the germinal tumors of humans in which it is highly malignant. It is probably best regarded as belonging, histogenetically, with the teratomas but not displaying the tissue differentiations that identify the teratoma. The cells are of indifferent embryonic types. Trophoblastic differentiation and demonstrable α-fetoprotein in the epithelial cells supports the diagnosis.

Teratocarcinoma, a neoplasm with features of teratoma and embryonal carcinoma, is reported in the horse.

Mixed germ cell–sex cord stromal tumor

These neoplasms are a combination of germ cells and cells derived from either the primitive sex cords or the stroma of the gonad. *Gonadoblastoma* is another name for this neoplasm. There is a suggestion that these have been missed and, hence, underreported. The lesions grossly are firm, white to tan, and expansile. Larger neoplasms may be hemorrhagic. *The histological features are a combination of seminoma and Sertoli-like cells with tubular structures intimately associated with germ cells.* Immunohistochemical staining with neuron-specific enolase for Sertoli cells and with vimentin for germ cells may confirm the dual nature of this neoplasm.

Other primary tumors

Adenomas and adenocarcinomas presumably originating from the rete testis are described in dogs and horses. These are tubulopapillary structures with scant supporting stroma. The papillae and anastomosing tubules are lined by small closely packed cells with scant cytoplasm either in single or multiple layers. Evidence of transformation from normal to neoplastic rete epithelium is a useful criterion for diagnosis, and it is desirable to exclude other teratomatous structures or distant primary tumor elsewhere. Immunohistochemically, cytokeratin is stainable in epithelium of the rete testis.

Reports of *mesenchymal tumors* of the testis are mostly of individual cases. They include leiomyoma and leiomyosarcoma, hemangioma and hemangiosarcoma, mast cell tumor, peripheral nerve sheath tumor, and histiocytic sarcoma, to name a few.

Neoplasia of the epididymis is a very rare event. Any tissue may transform, and metastatic neoplasia or involvement of systemic neoplastic conditions such as lymphoma may occur. Interstitial cell tumor of the epididymis of the cat is a recognized disease and arises from ectopic interstitial endocrine cells.

Miscellaneous diseases of the testis and epididymis

Sperm granulomas occur at any location that spermatozoa may be found. The most recognized syndrome is *sperm granuloma of the epididymal head*, a condition believed to be associated with blind-ending efferent ductules (see Ductular anomalies). It has been seen in virtually every species, except perhaps the cat.

Adenomyosis of the mesonephric ducts is a histological finding where *diverticula of the epithelium of the efferent ductule, epididymis, or deferent duct protrude through the muscular wall.* Spermatozoa may become entrapped and ultimately incite an inflammatory reaction. Hyperestrogenism may be an inciting cause. Adenomyosis is the suspected underlying defect when a sperm granuloma is found in a location apart from where blind-ending efferent ductules would be expected. Virtually every species has been reported to develop adenomyosis of the mesonephric duct.

The **rete testis** is a series of interconnected channels that join the seminiferous tubules to the efferent ductules. It has intratesticular and extratesticular segments. Spermatophagia occurs in this area, and immune reactions to spermatozoa may be manifested by inflammation in this region. There are two main primary diseases of the rete: *neoplasia and cyst formation.* The epithelial cells are the origin of adenomas and adenocarcinomas in horses, dogs, and other species. Cysts of this region are reported in the stallion, cats, and

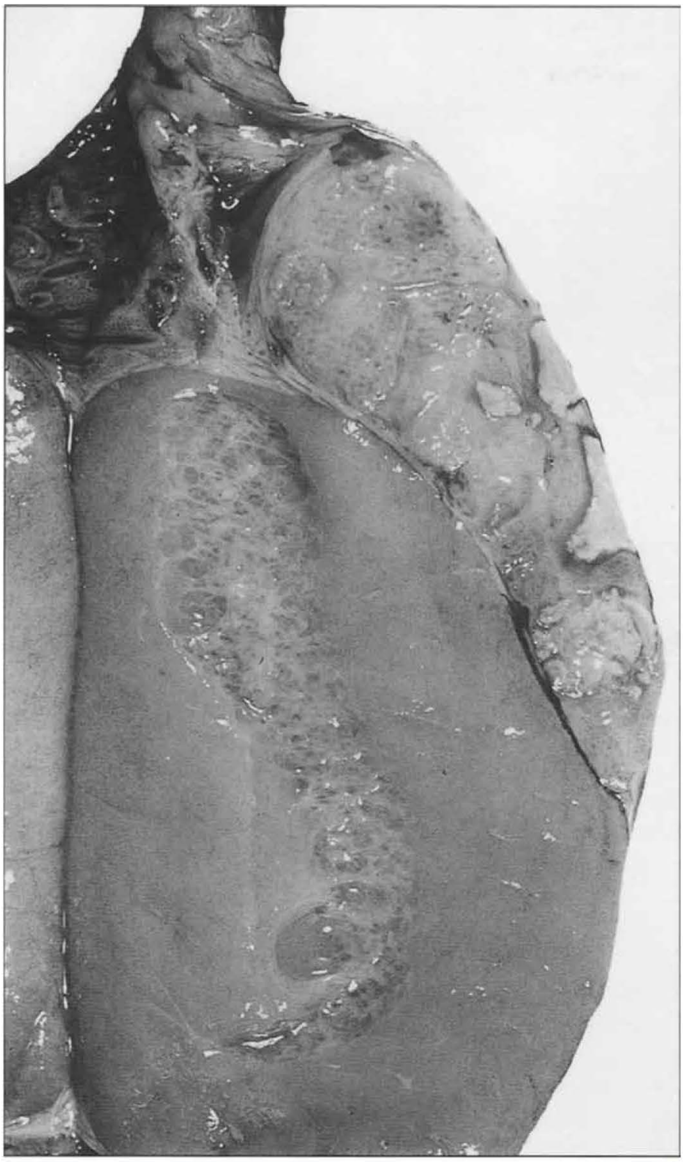

Figure 5.46 Dilation of rete tubules and the mediastinum testis secondary to obstruction and increased pressure caused by sperm granuloma of the epididymal head in a ram.

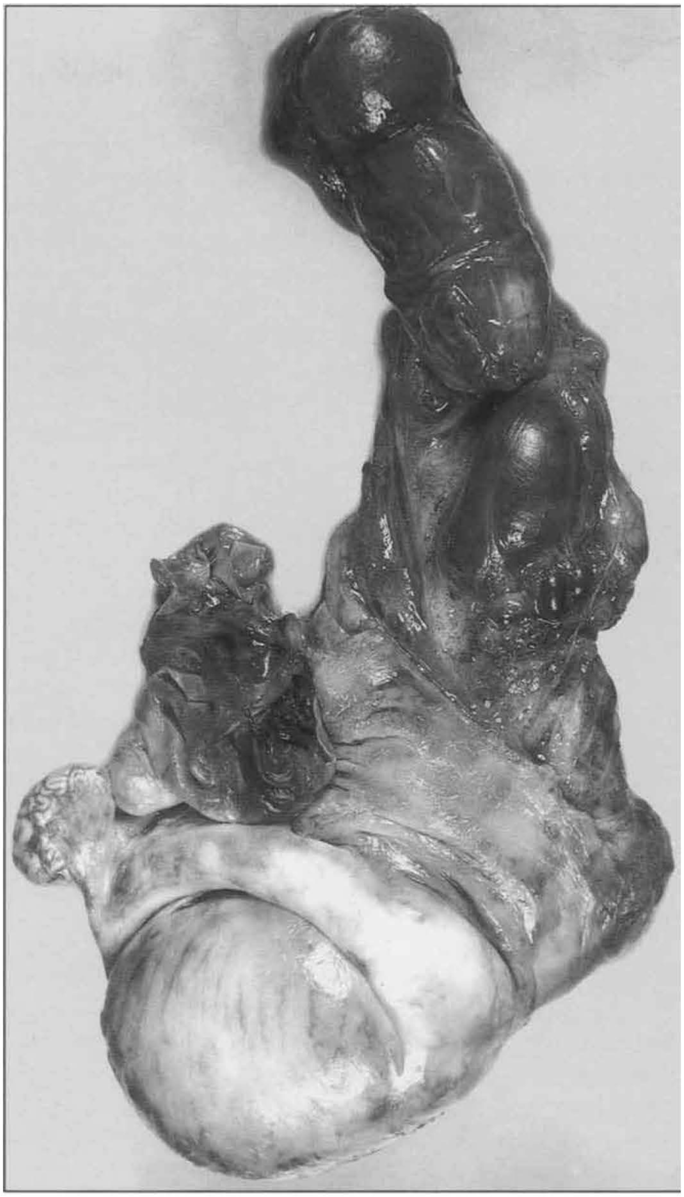

Figure 5.47 Varicocele with thrombosis in a stallion. The grossly dilated and thrombosed pampiniform plexus causes a large multilobular mass above the testis in the spermatic cord.

dogs. Secondary dilation of the rete testis occurs with obstruction of the efferent ductules or epididymis (Fig. 5.46).

SPERMATIC CORD

The spermatic cord is made up of the testicular artery, vein, and nerves, and the deferent duct. They are critical structures for the function of the testis and epididymis. Scrotal hernia and varices of the pampiniform plexus are probably the most commonly recognized disease of the spermatic cord. Most of the other diseases become differential diagnoses for these.

Varicocele

A varicocele is a dilation and tortuosity of the veins of the pampiniform plexus and the cremasteric veins. Varices of the spermatic veins are most commonly seen in old rams. They occur sporadically in other species, such as the stallion (Fig. 5.47), as an incidental finding or secondarily to conditions where there is constriction of the veins of the spermatic cord. Varices are seldom recognized unless they are thrombosed, and inexperienced persons may miss them. There is no concrete evidence that small varicoceles are detrimental, but the very large ones are, by virtue of their size and the reduced ability of the animal to raise the testis to maintain thermoregulation. The pathogenesis of varices in animals is not well understood. In humans, the left unilateral location is regarded as the result of altered hemodynamics from insertion of the testicular vein to the renal vein rather than directly to the vena cava. Evidence in humans with varicose veins of the legs suggests that the elastic properties of the walls of the veins and arterial flow are major factors and varicoceles in rams may be similar. Many rams and bucks have intimal sclerosis of the spermatic vessels but no varicocele.

Varicoceles appear as dark red nodules, 1–3 cm or more in diameter, enclosed in fascia of the spermatic cord proximal to the testis. Dissection of varicoceles may reveal large organizing laminated thrombi. *Differential diagnoses* of varicocele include neoplasia (mesothelioma), scrotal hernia, scrotal lymphadenitis, sperm granuloma of the deferent duct, and retained structures and cysts.

Varicocele in the ram is bilateral, or unilateral with no apparent predisposition as to side. Large varicoceles are always thrombosed and are associated with overt testicular degeneration, occasional thrombosis of testicular vessels, and reduced testis:body weight ratios, the latter possibly resulting from compromised thermoregulation in the testis. Detailed histological studies have revealed an apparently independent sclerosis involving almost 50% of both arteries and veins in the spermatic cord of rams. The arterial changes, which tend to be bilateral, consist of fibroplasia of the tunica intima. A variable degree of intimal and or medial mineralization may also be seen in branches of the testicular artery in the spermatic cords of rams and bucks. Apparent hypoplasia of veins of the spermatic cord has been observed in bulls associated with thickening and degeneration of the testicular artery.

Although studies in the bull have not demonstrated a direct connection between venous and arterial blood vessels of the pampiniform plexus, functional *arteriovenous anastomoses* through small vessels do occur in normal bulls, boars, and rams, and may represent a further means of thermoregulation of the testis. A large anastomosis of the spermatic artery and vein has been observed in the stallion associated with an abdominal testis.

Scrotal hernia

Scrotal or inguinal hernia is a rare condition in all species except the horse. It is reported in dogs, rams, and stallions. In rams, it tends to involve the left side. It is believed to be a genetic and recessive disorder.

In **stallions**, the disorder is either congenital and often resolves by 3–6 months of age, or it is acquired and is potentially life threatening because of intestinal strangulation. In the *congenital form*, a portion of the jejunum enters the vaginal sac; rupture of the vaginal tunics at birth may result in the loop of intestine lying in a subcutaneous location. In the *acquired form* in entire animals, there may be an association with exercise or some activity such as serving a mare. Left- and right-sided hernias occur with equal frequency. Herniation of the intestine usually obstructs vascular supply to the testis, necessitating castration at the time of surgical repair. The acquired form is very rare in geldings.

Miscellaneous diseases of the spermatic cord

Other lesions of the spermatic cord may involve any of the structures present, including the deferent duct, blood vessels, nerves, cremaster muscle, or tunics. Some of these diseases, particularly congenital anomalies, are described elsewhere in more detail.

Inflammation of the spermatic cord is **funiculitis**; it follows open castration. It may be acute and necrotizing, as is often seen in the pig, in those species in which there is ample opportunity for contamination, or it may be chronic, as in the typical "*scirrhous cord*" of horses and cattle. The nature of the infecting organisms determines the nature of the reaction. In the pig, it is often a necrotizing purulent response; there may be very little granulation tissue, and the cutaneous incision may not heal. In this species too, ascending infection provoking diffuse peritonitis, and tetanus, are common complications. The classic scirrhous cord of the gelding is a pyogenic infection, usually by staphylococci, which produces typical "botryomycosis," an exuberant granulation tissue enclosing multiple small abscesses and containing many fistulae.

A *pseudocyst* of the spermatic cord of a gelding is reported.

Neoplasms arising in these structures, or metastasizing from other locations may be found. Any of the structures can be involved, including fibrous tissue, smooth muscle, endothelium, or mesothelium.

Verminous granulomas caused by wandering larvae of *Strongylus* spp. are occasionally observed in the spermatic cord and testes of horses.

Sperm granuloma of the deferent duct is seen mostly as a sequel to vasectomy, but is occasionally observed as spontaneous disease.

Ectopic adrenal tissue is occasionally found in the spermatic cord.

Disease of the *scrotal lymph node* can be confused with disease of the spermatic cord. Caseous lymphadenitis in sheep and lymphoma in dogs are two relatively common diseases that may cause enlargement of the node and be mistaken for varicocele or some other abnormality. Drainage of lymph and therefore inflammatory infiltrates, spermatozoa, and metastases from intrascrotal neoplasia can be to the superficial inguinal, sub-iliac, or lateral and medial iliac nodes.

ACCESSORY GENITAL GLANDS

Vesicular glands (seminal vesicles) and ampullae

Anomalies of development

The chief congenital anomaly affecting the vesicular glands (seminal vesicles) and ampullae of the deferent duct is **segmental aplasia of the mesonephric duct**. This condition appears to occur most frequently, and has been most studied in the bull, in which it seems to be heritable. Aplasia or hypoplasia of this duct may affect any or all of the genital organs derived from it so that the deferent duct and epididymis may be simultaneously affected. Aplasia is mostly unilateral and the ampulla on the affected side is completely absent or rudimentary and the vesicular gland is markedly hypoplastic and sometimes cystic. Vesicular gland hypoplasia of variable severity may occur independently of aplasia of the ampullae or deferent duct. Other anomalies of the vesicular glands and ampulla of the bull include fusion of the vesicular glands (Fig. 5.48A) and

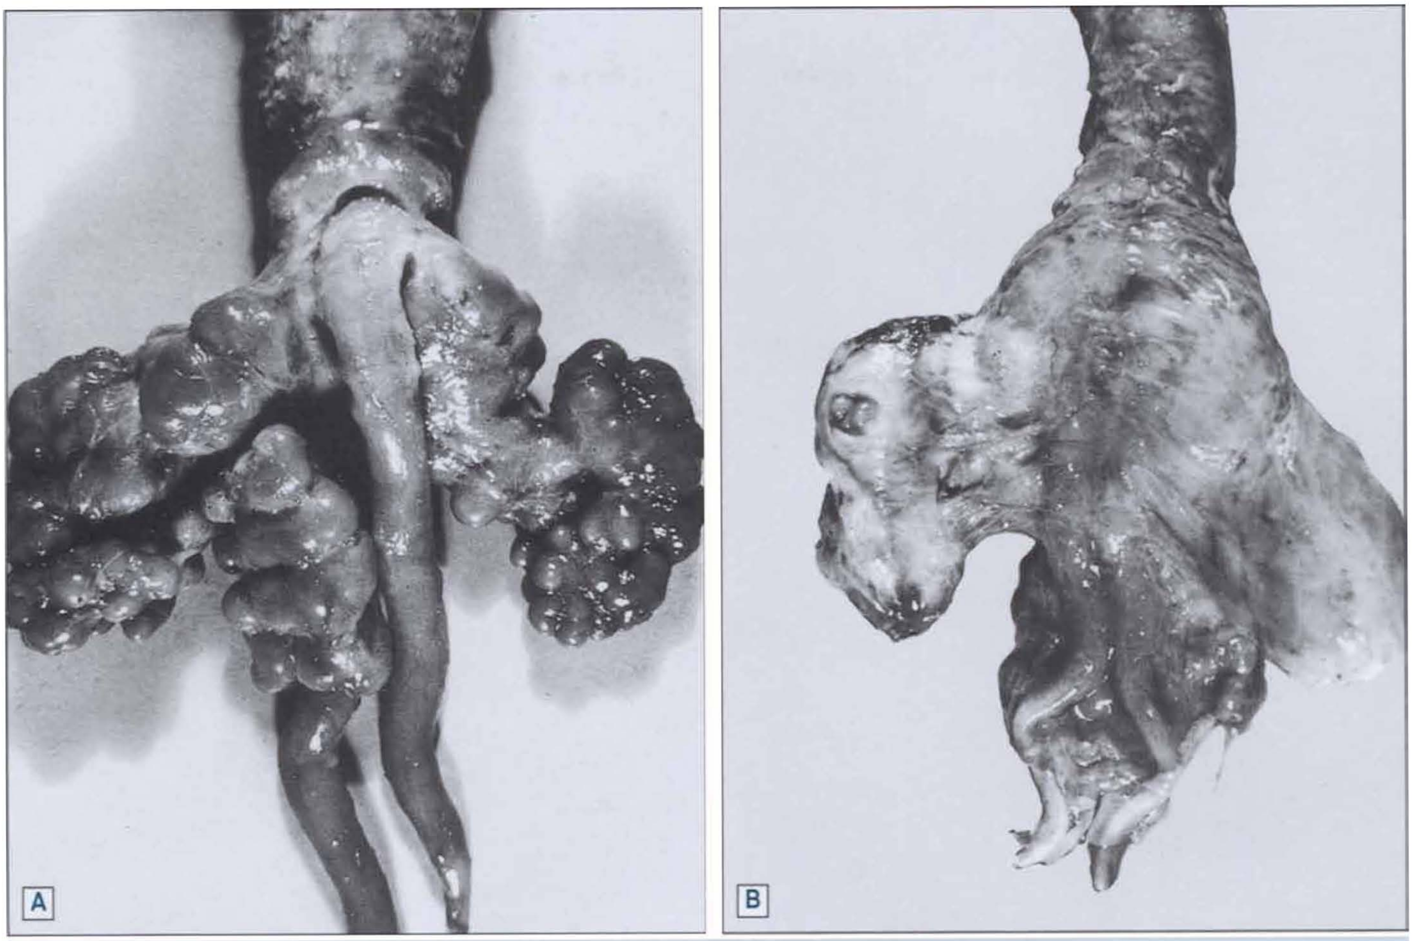

Figure 5.48 **A.** The **vesicular glands are fused** and there is a ventrally displaced ampulla in this bull. **B.** Chronic **vesicular adenitis** in this bull caused fibrosis and shrinkage of the glands.

appendages of the ampullae. There is variation in the relationship of ampullae to the vesicular glands in normal bulls; the ampullae are entirely dorsal to the vesicular glands in 40% of bulls, are entirely ventral to the vesicular glands in 40% of bulls, and in the remaining 20% of animals are intermediate. Realization of these anomalies and anatomical variations is important in rectal examination of bulls. Although the anomalies per se seem incidental, and unrelated to diminished fertility, evidence suggests that anomalous glands are predisposed to inflammation.

Cystic dilation of the lumina of occasional lobules, or a general dilation of duct lumina in one, and sometimes both, vesicular glands, occurs in bulls, horses, and swine.

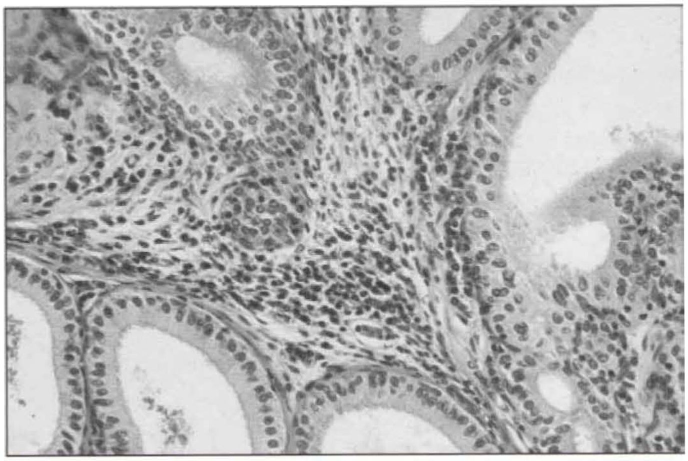

Figure 5.49 Microscopically visible **chronic vesicular adenitis** in a ram with *Brucella ovis* infection. Large numbers of lymphocytes and plasma cells are in the interstitium.

Inflammation of the vesicular glands

Vesicular adenitis, which is frequently accompanied by similar reactions in ampullae, is a common lesion in the bull, and is seen rarely in the stallion and boar (Fig. 5.48B). Macroscopically apparent vesicular adenitis is quite rare in the ram but histological lesions accompany the rather frequent localization of *Brucella ovis*, *Actinobacillus seminis*, and *Histophilus somni* (*Histophilus ovis*) in the vesicular glands and ampulla, in association with epididymitis caused by these organisms (Fig. 5.49). Typically, vesicular adenitis is characterized clinically by palpable changes in the vesicular glands on rectal examination, and by changes in the semen, particularly the presence of pus. Young bulls, less than 2 years of age, are frequently affected.

Two forms of vesicular adenitis are recognized in the **bull**, a *chronic interstitial form* characterized by a considerable increase in size, excessive fibrosis, firm consistency, and loss of lobulation, and a

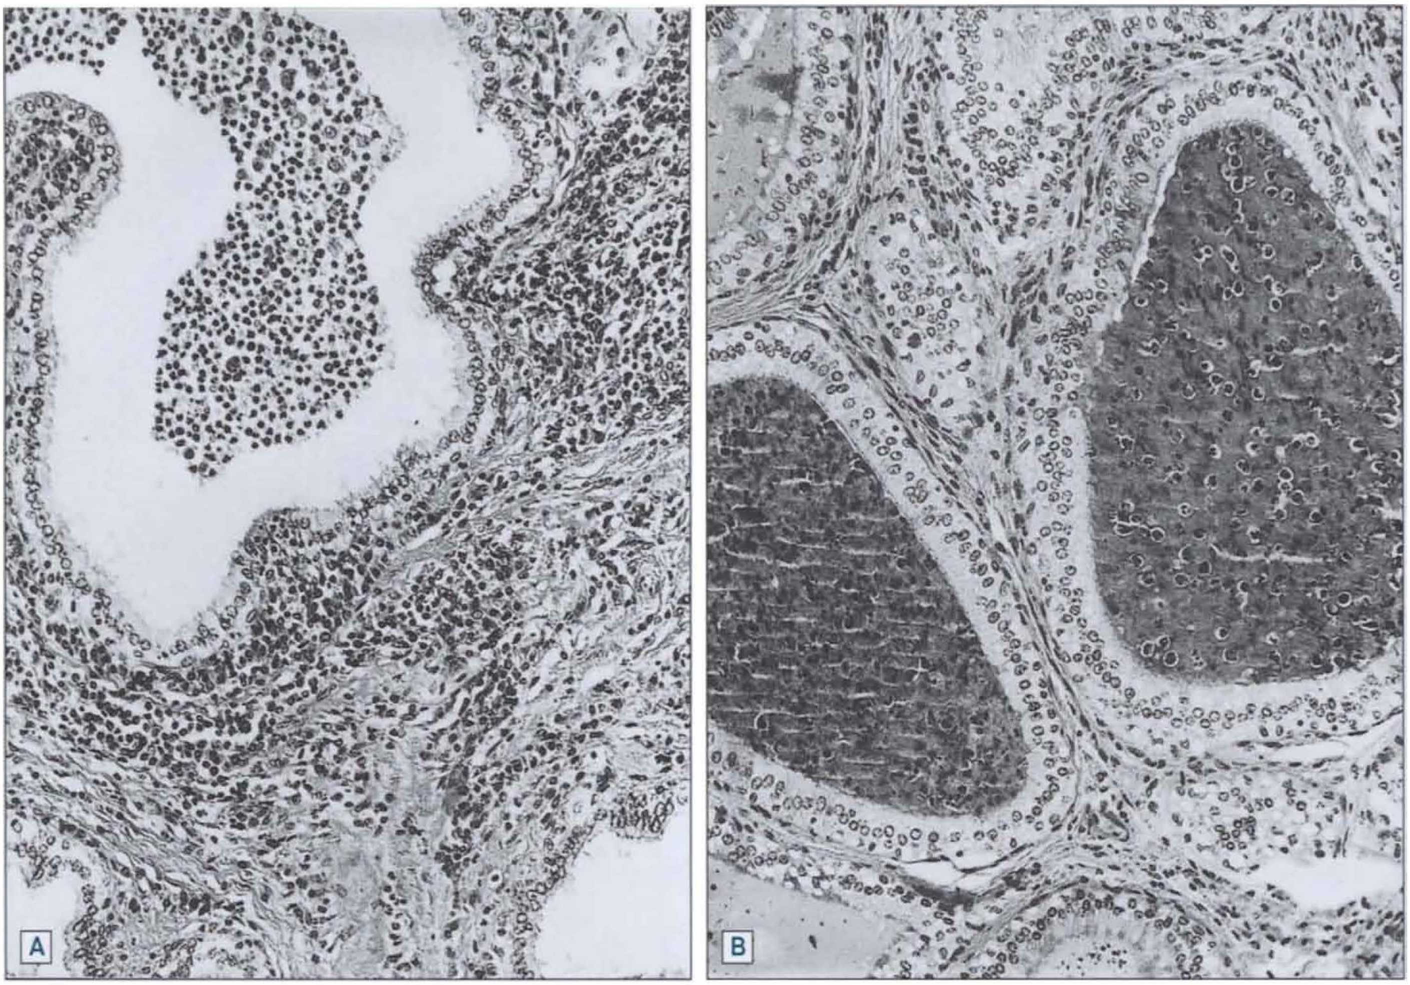

Figure 5.50 Histological lesions of **vesicular adenitis** in the bull. **A.** Chronic interstitial vesicular adenitis with lymphocytes, plasma cells and fibrous tissue in the interstitium. Glandular lumina contain neutrophils. **B.** Acini are filled with basophilic debris.

predominantly *degenerative form* characterized by at most a slight increase in size and consistency.

Microscopically, the chronic interstitial form is characterized by fibrosis and cellular infiltration of stroma with lymphocytes, plasma cells, histiocytes, neutrophils, and occasional eosinophils (Fig. 5.50A). The epithelium usually is normal but may be metaplastic in some areas. Acini contain a small amount of finely granular eosinophilic material, occasional neutrophils and desquamated epithelium. In the predominantly degenerative form of vesicular adenitis, only a slight increase in stroma is observed, but leukocytic infiltration is often present. In addition, neutrophils, sloughed epithelium, and intensely basophilic material are present in the acini in clumps or strands (Fig. 5.50B).

Numerous *infectious agents* may be isolated from bovine vesicular adenitis, but the precise roles of most have yet to be determined. In chronic vesicular adenitis, bacteriological investigations are often negative. *Arcanobacterium pyogenes* appears to be the most common isolate, and lesions in general are those of chronic interstitial vesicular adenitis. Large abscesses may be present also. These may involve adjacent tissue, and adhesions and fistulas form with the rectum or bladder. Staphylococci and streptococci generally do not form large abscesses, but more often small focal or diffuse suppurative inflammation. Vesicular adenitis caused by *Brucella abortus* is fibrinopurulent, progressing to necrosis, suppuration, and dystrophic mineralization; granuloma formation is rarely observed. Tuberculous vesicular adenitis causes a great increase in the size of vesicular glands with characteristic nodulation and caseation.

Several viruses, including the virus of infectious bovine rhinotracheitis–infectious pustular vulvovaginitis (*Bovine herpesvirus 1*), may infect the accessory genital glands of the bull. Clinical signs of vesicular adenitis in such cases are reported to be mild and transitory. The vesicular glands and prostate are the most productive sites for viral replication in *Bovine viral diarrhea virus* infection in bulls, but neither gross nor microscopic lesions are observed. *Mycoplasma bovigenitalium* and ureaplasmas have been isolated from bulls with vesicular adenitis, and unequivocal lesions have resulted from experimental infection with these organisms and *Mycoplasma bovis*. Apart from a slight to pronounced infiltration of eosinophils into these lesions, they are nonspecific, and it is unclear to what extent mycoplasmas cause spontaneous vesicular adenitis. *Mycoplasma bovigenitalium* can be isolated from the vesicular gland secretions from a large proportion of normal pubescent bulls. As with the mycoplasmas, *Chlamydophila* spp. have been isolated from the semen and epididymides of bulls, and its possible role in vesicular adenitis has yet to be clarified. The vesicular glands may also be an important site for localization of *Leptospira* spp. *Leptospira interrogans* serovar *hardjo* has been isolated with equal frequency from vesicular glands and kidneys of naturally infected bulls, thereby suggesting the possibility of venereal transmission.

The *pathogenesis* of bovine vesicular adenitis is as yet unresolved. Hematogenous infection of the glands from a primary point of infection elsewhere seems probable in most cases but ascending infection from the urethra and infection via peritoneal fluid, perhaps following navel infections during calfhood, are also possible. Establishment of infection may be aided by stress, reflux of urine or semen into the vesicular glands, and by congenital defects in the duct system of the pelvic organs.

In **sheep**, **goats**, and **pigs**, vesicular adenitis is of lesser importance than in the bull, but it occurs in brucellosis caused by *Brucella ovis, Brucella melitensis*, and *Brucella suis*, respectively. The characteristic lesion is chronic, and resembles that seen in the bull (Fig. 5.49). In boars, abscessation of the vesicular glands and prostate may accompany orchitis caused by *Burkholderia pseudomallei*. Abscesses in the vesicular glands of barrows may be the result of infection at the time of castration.

In the **stallion**, purulent, abscess-forming vesicular adenitis has been described, but appears to be uncommon. Following experimental infection with *Equine arteritis virus*, virus is shed in semen of experimentally infected stallions for months, and the ampullae and bulbourethral glands seem to be predilection sites. It is unclear whether there are lesions in infected tissues, or associated spermatozoal abnormalities. Bacterial vesicular adenitis and ampullitis occur sporadically and may be a cause of "colic."

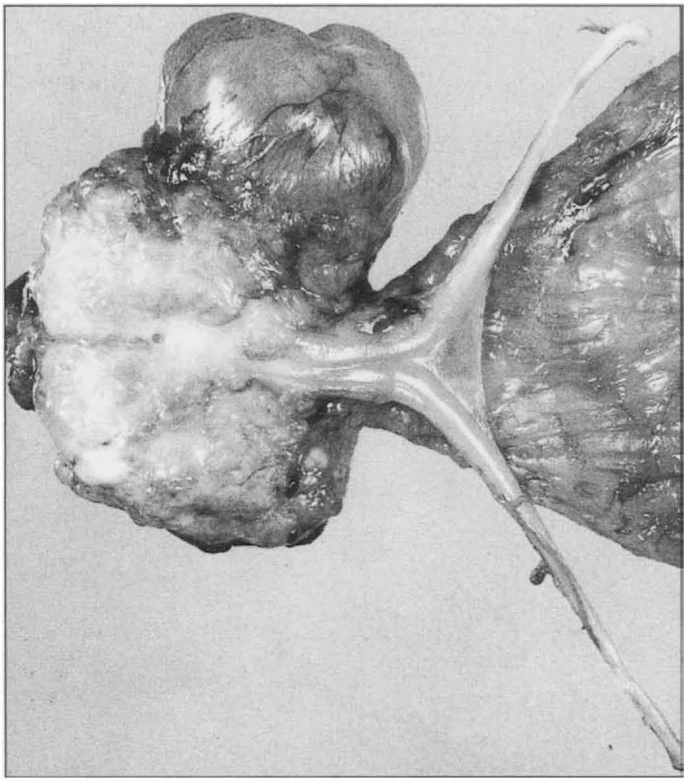

Figure 5.51 Paraprostatic cyst distorting the contour of the prostate in a dog.

Prostate and bulbourethral glands

These accessory genital glands are both derived from urogenital epithelium and their responses to some adverse influences are similar. Studies on the accessory genital glands of normal bulls and rams have demonstrated that a protective local secretory immune system is present and especially involves the bulbourethral glands and prostate, which both have a predominance of IgA-containing cells in subepithelial locations.

Anomalies of development

Anomalies of the bulbourethral gland include *congenital retention cysts* in bulls, rams, and cats, and *aplasia, hypoplasia, and fusion* in bulls. *Melanosis* of the bulbourethral glands has been observed in the bull and in swine. Malformations of the prostate are infrequent and are usually seen together with anomalies of the remaining genitalia – especially in intersex states and in cryptorchidism. In some dogs, the dorsal median groove of the prostate may be indistinct so that the bilobed nature of the gland is not clearly evident. Other prostatic anomalies include the *prostatic appendage in the bull* with polyp-like protrusion of prostatic tissue into the urethral lumen, and congenital retention cysts in the bull and cryptorchid boar.

Prostatic cysts in the dog may be congenital or be secondary to hyperplasia, neoplasia, or inflammation (see below). Classification of prostatic cysts in the dog into four types – *multiple cysts associated with prostatic hyperplasia, retention cysts, paraprostatic cysts, and cysts associated with squamous metaplasia* – has been proposed. Although their precise origin is still unclear, paraprostatic cysts probably result from anomalous development. Most cysts appear to be attached to the prostate at a small localized area but without a definite stalk (Fig. 5.51). The smaller cysts are up to ~7 cm in diameter and have a wall 2–5 mm thick, whereas larger cysts may be up to 24 cm long and 14 cm in diameter and contain much collagen and even bone in their walls. Both types of cysts may be lined by epithelium that appears to be secretory. Accumulations of fibrin on the inner aspect of the larger cysts, as well as cauliflower-like bony lesions extending into the lumen, are common. Cysts may rarely become infected and rupture but their content is almost always sterile and is devoid of pus, urine, and spermatozoa. It has been suggested that such cysts arise from vestiges of the paramesonephric duct, the uterus masculinus, but most reported cysts appear to have arisen from one or the other prostatic lobe. Enlarged remnants of ducts that form prostatic or paraprostatic cysts may be expected to arise in the dorsal aspect of the prostate and have their origin in the midline. Where such cysts are bilobed and lined by simple columnar to pseudostratified columnar epithelium that resembles endometrium, their designation as *cystic uterus masculinus* is justified. Cystic enlargement, which occurs mostly in old dogs, appears to be stimulated by estrogenism, as in response to a Sertoli cell tumor, and may cause constipation, dysuria, or anuria.

A *uterus masculinus* is also frequently observed in males of other species (Fig. 5.52). As in the dog, it may be cystic or communicate with the urethra.

Inflammation of the prostate and bulbourethral gland

Inflammation of the bulbourethral gland in the bull often accompanies vesicular adenitis, which it resembles both in causation and tissue response. Concretions may result from chronic inflammation.

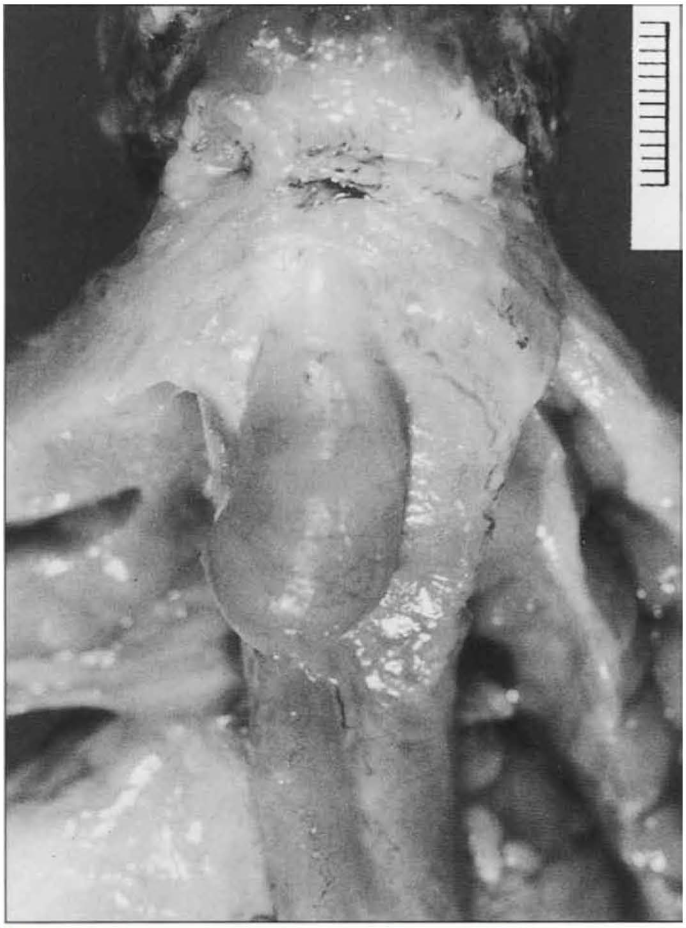

Figure 5.52 Cystic uterus masculinus (center) overlies the ampullae of this bull.

Prostatitis is common in the dog. It is often a disease of older dogs in which hyperplastic prostatic changes are present. The inflammatory changes contribute to the enlargement in a significant proportion of the cases, but the disease may occur in younger dogs with normal prostates. The infecting agents are urinary pathogens, *Escherichia coli*, *Proteus vulgaris*, streptococci, and staphylococci, which invade via the prostatic urethra.

Prostatitis is often acute, with systemic signs of illness, and about two-thirds of affected dogs have a history of urinary tract signs that include gross blood and or pus in the urine, urethral discharge, incontinence, or dysuria. Except for dramatic elevations in neutrophil counts with prostatic abscesses, hematological data are mostly equivocal, so that cytological evaluation and culture of prostatic fluid collected by prostatic massage or ejaculation is needed to assist in the differential diagnosis of prostatic disease in the dog.

Acute prostatitis is a diffuse or focal suppurative process with a tendency to abscess formation. The abscesses may be minute and multiple, or large with confluent areas of necrosis. The larger abscesses fluctuate on capsular palpation. Such abscesses may lead to metastatic sepsis, septicemia, peritonitis, and death, especially if there is sudden rupture.

In *diffuse prostatitis*, the gland is often asymmetrically enlarged, congested, and edematous (Fig. 5.53) with a soggy consistency, and pressure causes welling of pus over the cut surface. Depending on the duration and severity of the inflammation, the reaction may be centered on the acini with mild exudation and only slight stromal involvement, or a neutrophilic infiltrate may pervade all structures (Fig. 5.54A). Localization in and destruction of acini proceeds to abscess formation and these may become confluent, converting the whole gland into a multiloculate abscess cavity, but this is unusual. Acute inflammation may resolve and leave only extensive scarring, or it may become chronic, especially if ducts are obstructed, and the infection then tends to persist in small walled-off foci.

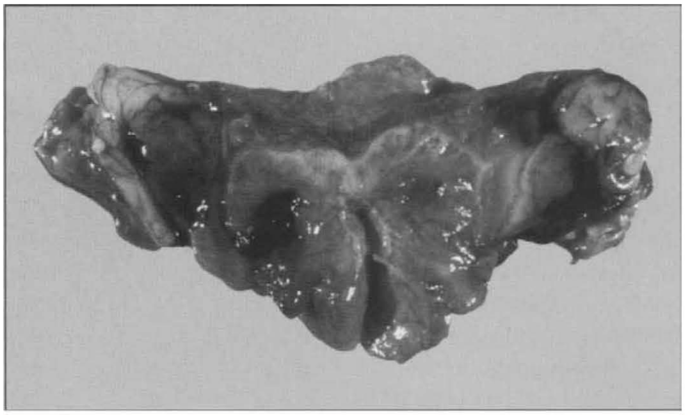

Figure 5.53 Transverse section of a canine prostate with **acute prostatitis**. Hemorrhage and edema involve the prostate and the periprostatic tissues.

Chronic prostatitis in the dog is also a common lesion (Fig. 5.54B). The prostatic epithelium is atrophic and its cytoplasm loses its characteristic eosinophilic staining quality. The lumina of the gland contain a variable number of neutrophils and macrophages, and debris. The inflammation is apt to involve the gland segmentally and may spare large portions. Aggregates of lymphocytes in the fibromuscular stroma, especially about the ducts, are very common.

Prostatitis is a constant feature of *Brucella canis* infection. Typically, involvement is extensive but lobular in distribution, and consists of a generalized lymphocytic infiltration with destruction of adjacent epithelium and associated fibrosis. Prostatitis may become emphysematous in the presence of gas-forming organisms. Systemic fungal infections, such as that caused by *Blastomyces dermatitidis,* may involve the prostate.

Metaplasia and hyperplasia of the prostate and bulbourethral gland

Reversible enlargement of the bulbourethral glands with squamous metaplasia, hyperplasia, and cystic dilation occurs in wethers ingesting strains of *clover possessing high estrogenic potency*, e.g., *Trifolium pratense, T. repens, T. subterraneum*. In wethers, but not in entire male sheep, a few weeks grazing on potent green clover pastures provides adequate estrogenic stimulus for the induction of profound and extensive metaplastic changes in the accessory sex organs, particularly the bulbourethral glands. The bulbourethral glands become enlarged and firmer than normal and are marbled on cut surface. They may also contain cysts, and in a small percentage these cysts may become enormous and cause fluctuating swelling of the perineal region (Fig. 5.55). The large cavity fills with urine and cellular detritus and communicates with the lumen of the urethra through the dilated pores of bulbourethral glands in the dorsal wall of the pelvic urethra. The epithelial hyperplasia, together with the formation

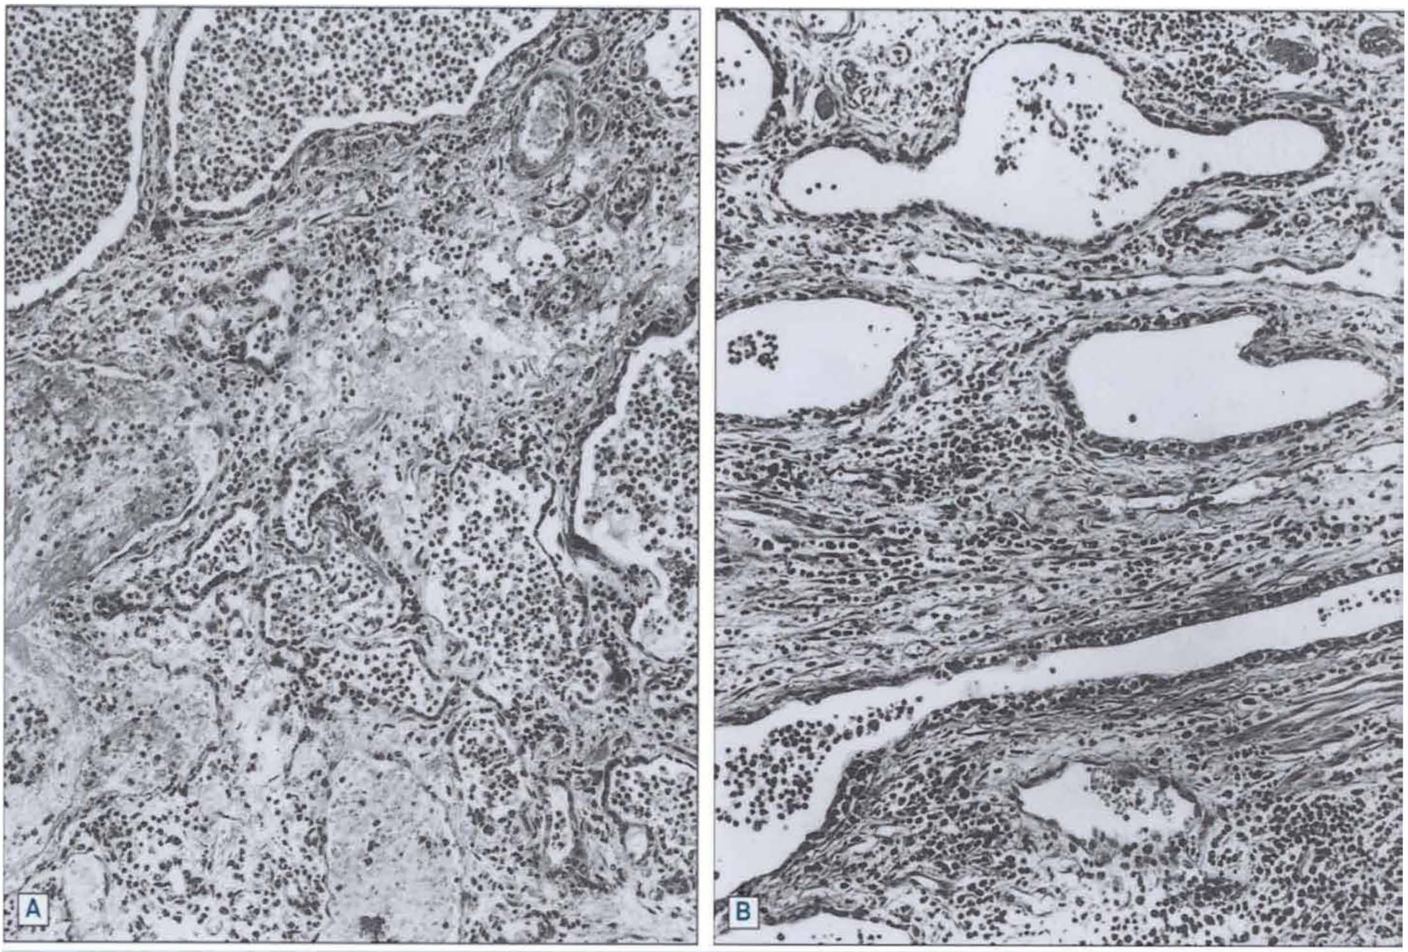

Figure 5.54 A. Histological appearance of **acute prostatitis** with abundant neutrophils within glandular lumina, and interstitial edema and leukocytes. **B. Chronic interstitial prostatitis** with lymphocytes and plasma cells with abundant fibrous tissue in the interstitium of the prostate of a dog.

of cellular casts, may produce urethral obstruction with death. Prolapse of the rectum is not uncommon. Cysts of the uterus masculinus occur and castrated males show mammary development (for effect on females, see Vol. 3, Female genital system). The *prostatic changes* consist of squamous metaplasia with conversion of the acini to keratinaceous cysts. There is also increased stroma in the prostate, and the changes are grossly visible as chalky or yellow streaks and flecks. In addition, the prostatic urethra may show metaplastic changes.

After *stilbestrol* administration, comparable changes have been observed in the bulbourethral glands, prostate, and vesicular glands of feedlot lambs and bull calves. In bulls, histology and quantitation of cytokeratin by immunohistochemistry may be used to detect illegal use of estrogenic compounds as growth promotants.

Marked squamous metaplasia of glandular genital organs, but particularly the vesicular glands of bulls, occurs following ingestion of *chlorinated naphthalenes*. Nodular hyperplasia of the bulbourethral glands of rams occurs occasionally.

Hyperplasia–hypertrophy of the prostate is observed in the bull, but it commonly occurs only in the dog; the organ is more-or-less diffusely involved, although in some instances normal or atrophic lobules may be interspersed in small numbers among hyperplastic ones. Some degree of hyperplasia is often evident in dogs 4–5 years of age, and the prevalence and degree increase with advancing years, such that 80% or more of mature or old dogs may have enlarged prostates. Squamous metaplasia of the epithelium of the prostate gland in the male dog may occur spontaneously in association with *neoplasia of the testes*, particularly Sertoli cell tumors, or following the administration of *estrogens*. The metaplastic change may involve acini in all parts of the gland as well as the prostatic urethra, uterus masculinus, and ducts. Affected epithelium is converted to stratified squamous, from the surface of which squames are shed into the lumen (Fig. 5.56). Neutrophils and macrophages are often numerous in lumina containing squames that have become fused into amorphous masses. Squamous metaplasia is associated with increased proliferation of basal cells. Although squamous metaplasia of the canine prostate predisposes it to inflammation, there is no evidence that this is a preneoplastic change. Squamous metaplasia of the prostate, comparable to that in the dog, has also been observed in swine. In cats, following estrogen administration, prostatic enlargement with epithelial hyperplasia and cystic dilation of glands occurs, but metaplastic cornification is restricted to urethral epithelium.

Enlargement of the prostate is frequently associated with *constipation*, presumably caused by pressure on the rectum. Less common, but more important, is *interference with urination*. It is not agreed just why urinary retention occurs. Compression with stenosis of the prostatic urethra has been advanced as an explanation, but is unsatisfactory because, at least postmortem, it is impossible to demonstrate any compression of the urethra, and because in the living animal incontinence

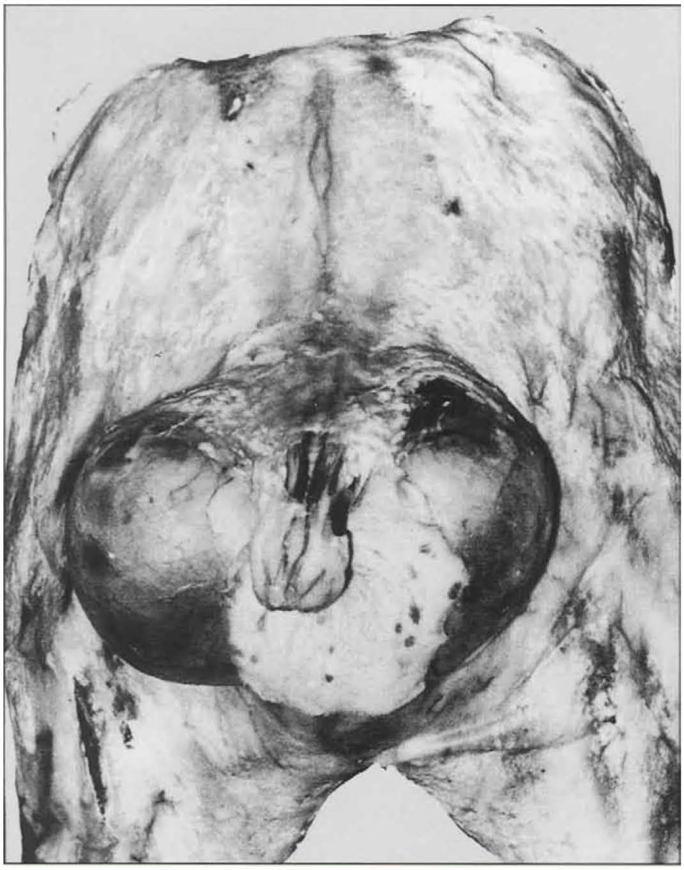

Figure 5.55 Phytoestrogenism causing massive enlargement of the bulbourethral gland in a wether.

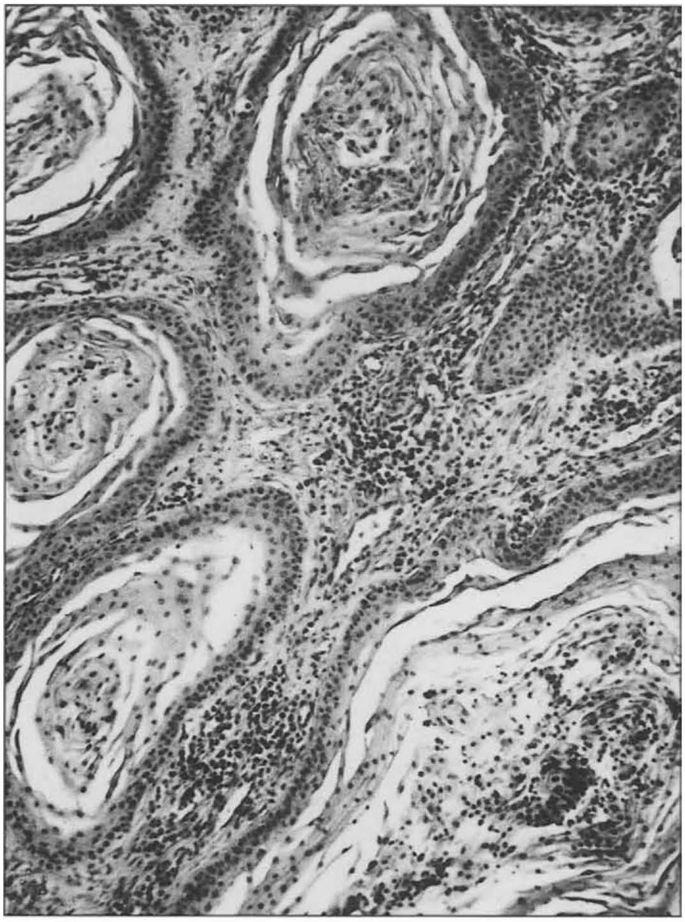

Figure 5.56 Squamous metaplasia of the glandular acini in the prostate of a dog. There are also interstitial infiltrates of lymphocytes.

is common and slight manual pressure on the bladder will serve to eliminate urine. Nor is the urethra completely surrounded by the prostate gland. It is possible that pressure of the enlarged gland on the sacral parasympathetic outflow causes paresis of the bladder. It is also possible that attenuation of the urethral lumen by longitudinal stretching may contribute in those cases in which the prostatic enlargement is sufficient to cause its displacement forward out of the pelvic cavity. Acute infections of the urinary tract and hydronephrosis often complicate the urinary obstruction.

There is little doubt that hormonal imbalances are important causes of prostatic hyperplasia. Hyperplasia does not occur in castrated dogs and castration is a useful therapeutic measure, although there are rare exceptions in which an adrenocortical tumor in a castrated dog has been associated with hyperplasia. *An altered androgen:estrogen ratio seems to underlie prostatic hyperplasia in dogs.* Two phases in the development of lesions are suggested. In the first phase in young dogs, actual epithelial hyperplasia is associated with normal testicular interstitial endocrine cells and normal androgen production, but with the secretion in the testes of an as-yet-unidentified estrogen-like molecule. In the second, cystic, phase there is decreased androgen production and decreased activity of testicular interstitial endocrine cells but continued production of the estrogenic substance. Importantly, however, although levels of circulating testosterone may decrease in old dogs, actual concentrations of dihydrotestosterone in hypertrophied or hyperplastic tissue are increased. Also it has been demonstrated that in such tissue in aged Beagles, nuclear androgen receptors are elevated. Therefore, estrogens appear to act synergistically with androgens to potentiate hyperplasia and act directly on the prostate. It is unclear in spontaneous prostatic hyperplasia, however, whether and to what extent estrogen induces accompanying stromal changes.

The hyperplastic gland is almost invariably enlarged, sometimes up to four times its normal size, and the surface is irregularly nodular (Fig. 5.57A), in some cases obscuring the normal bilobed appearance. Palpably fluctuating cysts and venous and lymphatic ectasias may be present beneath the capsule. The appearance of the cut surface varies depending on the degree of acinar and stromal hyperplasia and on the presence and size of cysts. The lobules vary much in size and may be poorly defined, or well defined if there is a prominent increase in size of the interlobular trabeculae.

The glandular elements are often spongy, and close examination reveals numerous small cysts containing milky fluid. The larger readily visible cysts are irregularly distributed, but the largest ones tend to be located beneath the capsule. The prostatic urethra may be somewhat distorted with small yellow elevations of the mucosa corresponding to the papillae of the excretory ducts. Microscopically, the structure is very diverse and consists of adenomatoid hyperplasia, stromal hyperplasia, and condensation, and cystic formations variously interspersed (Fig. 5.57B). The adenomatoid or acinar hyperplasia consists of epithelial hyperplasia leading, as in the thyroid gland, to papillary proliferations into the lumen, but always in a single layer on an intact basement membrane. Within the same lobule, some acini may be cystic, and these are of irregular size, rounded, and lined by

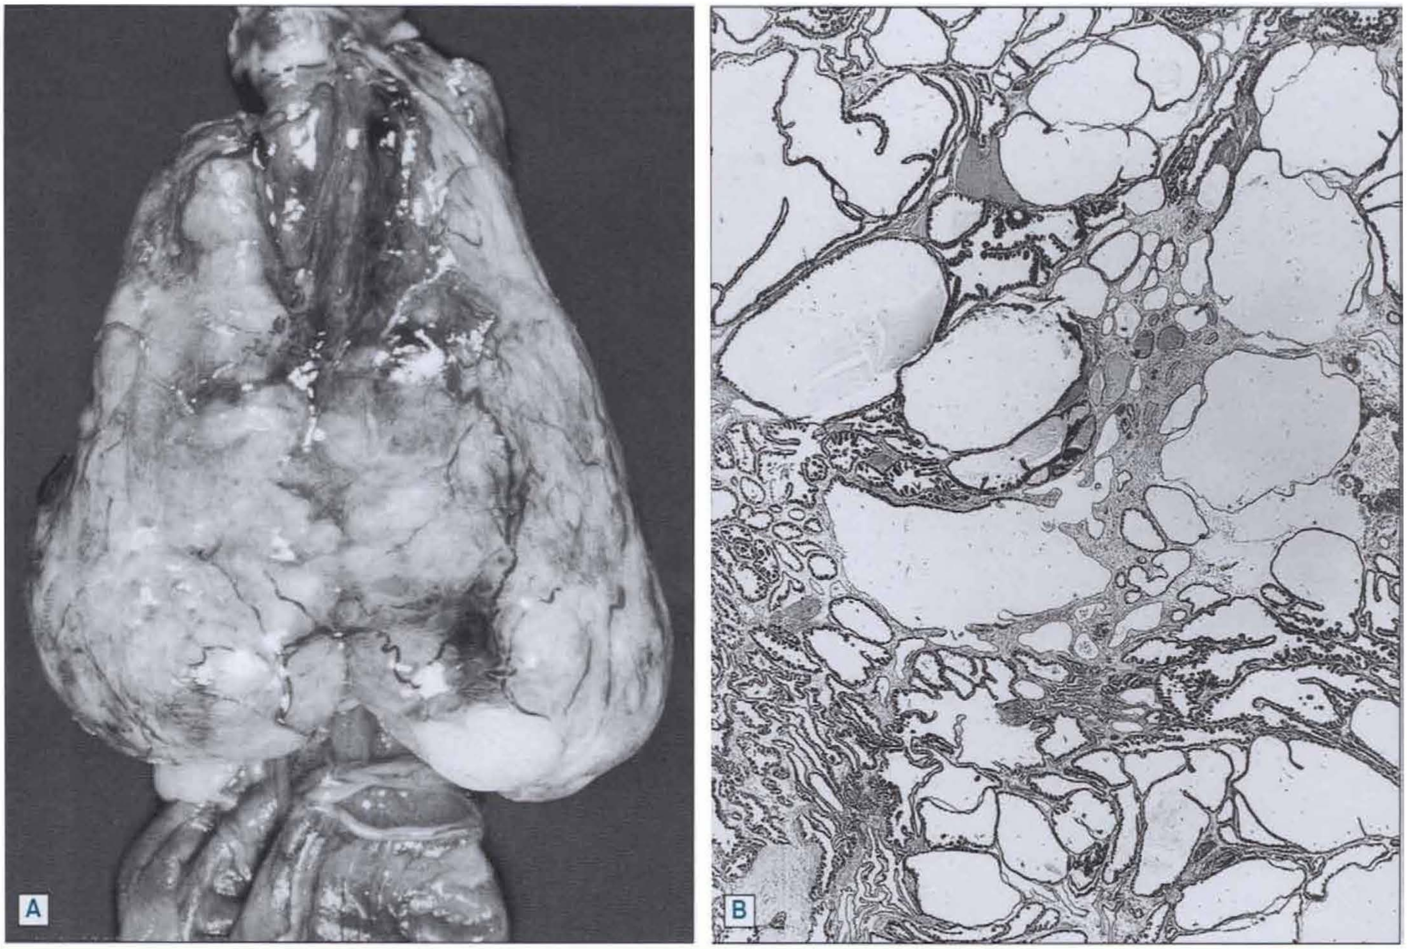

Figure 5.57 A. Prostatic hyperplasia in a dog typically causes almost symmetrical enlargement of the prostate. **B.** Microscopically, the glands are both cystic and hyperplastic.

epithelium that has become pressed and flattened. There may be secretion in the lumen but usually not. The interlobular connective tissue is frequently and irregularly increased in amount and condensation, and may exist as broad sheets with some extension into the intralobular stroma. In most instances, this interstitial tissue contains accumulations of mononuclear inflammatory cells, but the infiltrates do not involve the epithelium or acinar lumen.

There is no clear distinction between a normal prostate and one that is in the early stages of hyperplasia, although arbitrary decisions may be made on the weight or size of the gland relative to body weight. The relative weight corrected for age is fairly consistent, except in Scottish Terriers in which the relative weight of the prostate is about four times that of any other breed. Although estrogens in some cases are therapeutically effective in causing temporary regression of an enlarged prostate, these hormones in suitable dosage cause rapid enlargement of the gland.

Hypertrophy induced by estrogen per se is distinguishable by virtue of squamous metaplasia in the gland, and frequently in the uterus masculinus also.

Neoplasms of the prostate and bulbourethral gland

Neoplasia of the accessory genital glands is rare in all domestic animals. Hemangiosarcoma has been observed in the bulbourethral gland of the goat.

Major interest centers on **prostatic carcinoma in dogs**. There are different opinions about the origin and classification of neoplasia of the canine prostate. While the origins may be from acinar or ductular epithelium, neoplasia may also arise from the pelvic urethra and this seems especially plausible in dogs castrated prior to puberty (Fig. 5.58). Studies indicate that the glandular types of carcinoma are correlated with the lifetime exposure of testicular hormones. Immunohistochemistry has been used to separate transitional cell (urothelial) carcinoma arising in the urethra from prostatic glandular carcinoma (adenocarcinoma), but many studies do not appear to make the distinction. There is also the problem of dealing with mixed neoplasia wherein there are glandular and urothelial elements. Attempts to differentiate neoplasms are made difficult because they have a similar cell of origin. *It seems better to group the neoplasia as carcinoma of the prostate, and to acknowledge that glandular, urothelial, squamoid, or mixed types occur.*

Carcinoma of the prostate is uncommon. Neoplasia of the canine prostate is considered not to result from hyperplasia. *The cause of prostatic carcinoma is unknown* but, as with hyperplasia, it seems clear that the neoplasm may develop in an environment of hormonal imbalance, probably with other causative factors also being involved. Prostatic neoplasia is not causally related to testicular neoplasia. Castration has been shown to increase the risk of development of prostatic carcinoma.

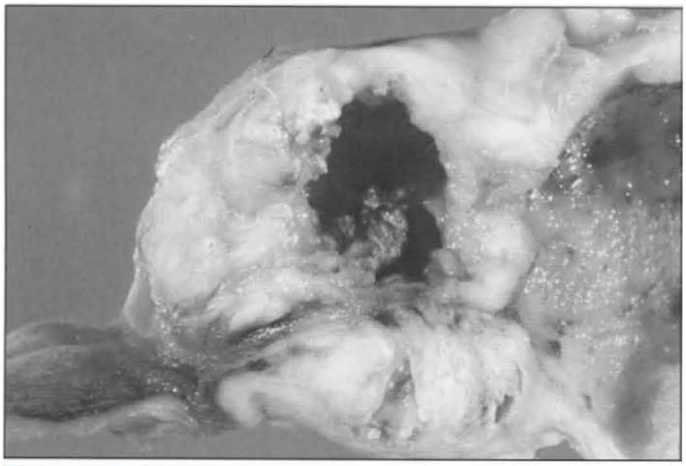

Figure 5.58 . Carcinoma of the prostate in an older dog castrated before puberty. The phenotype was a **transitional cell carcinoma** that had a small primary with central cavity of necrosis. This neoplasm was widely metastatic.

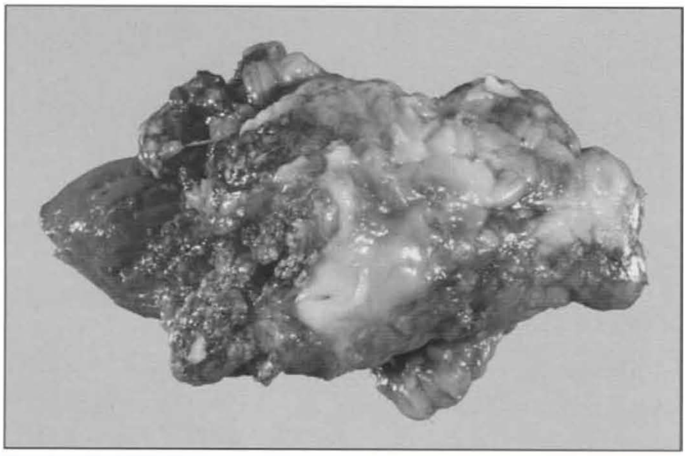

Figure 5.59 Carcinoma of the prostate in a dog. The phenotype of this carcinoma was an **adenocarcinoma**. Extensive invasion of the neoplasm into the surrounding tissues with filling of the pelvis is evident. No distant metastases were found.

Prostatic carcinoma is seen mostly in old dogs, especially those older than 10 years. Clinical signs are those of prostatic disease generally, but dogs with carcinoma seem more likely to exhibit emaciation and hindlimb locomotory disturbances, apparently due to metastasis of the tumor to the lower lumbar vertebrae, bones of the pelvis, and perhaps long bones of the rear limbs. Metastasis to bone is common, and is accompanied and probably preceded by visceral metastasis. In addition to the pelvis and lumbosacral spine, metastasis may involve the ribs, scapula, or digits. Bone metastasis may result from spread of neoplastic cells in the vertebral venous plexus, systemic circulation, or direct extension. Macroscopically, enlargement of the prostate with carcinoma is more likely to be asymmetric and irregular than is the case in hyperplasia (Fig 5.59).

A severe fibrosing reaction to invading tumor cells may be evident, and the neoplasm usually is quite hard, sometimes containing foci of ossification. The capsule of the prostate and adjacent organs often is invaded by the neoplasm, which may be adherent to the pubis or pelvis probably more commonly than in prostatic hyperplasia. Cyst formation in association with the neoplasm is common. Neoplastic tissue may extend into the sublumbar area, and metastasis to iliac, lumbar and pelvic lymph nodes, bone, kidneys, bladder, lungs, liver, heart, mesentery, and omentum occurs. Neoplastic cells may also be observed in the urine and occasionally in blood smears. Prostatic carcinoma metastatic to the regional lymph nodes and urinary bladder, but not the lungs, has been associated with hypertrophic osteopathy. Histological confirmation of the prostatic origin of metastases in bone and other tissues may be aided by immunohistochemistry. However, whereas both normal and hyperplastic canine prostatic epithelium label strongly with antibodies to both canine and human prostatic antigen, most reported canine prostatic carcinomas did not.

Microscopically, *it is important to note that most prostates with carcinoma will also contain areas of hyperplasia*, so on preliminary examination features of hyperplasia, and especially the tendency or otherwise for cells to be arranged on a basement membrane, need to be assessed. Also, as with malignant neoplasia generally, careful attention needs to directed to the extent of any associated necrosis and inflammation and the likely contribution of tumor growth in causing this. Heterogeneity is a feature of prostatic carcinoma. About one-third are adenocarcinomas with glandular differentiation including typical variation in acinar size, shape, and spacing, acini lined by cuboidal or columnar cells with enlarged nuclei and prominent nucleoli, sometimes a signet-ring pattern of tumor cells, and mucin often present within lumina of acini. A greater proportion of prostatic carcinomas, however (~50%), show mixed morphology, so that even within one tissue section, two or more patterns of differentiation – such as urothelial, squamoid, or sarcomatoid, as well as glandular – may be present. In the urothelial type, cells with round nuclei are present in dense nests. In squamoid tumors, closely packed non-keratinizing epithelial cells with abundant cytoplasm have prominent intercellular bridges. Sarcomatoid change, which is characterized by spindle-shaped nuclei in tumor cells, seems rarely, if ever, to predominate.

Prostatic carcinoma is described in the **cat**, in which the prostate is normally placed more caudally than in the dog and covers the urethra dorsally and laterally. As in the dog there is a history of dysuria and hematuria. Affected prostates measure 2 cm or greater, are white to cream, and microscopically have acinar or ribbon arrangement of pleomorphic epithelial cells. Mitoses are frequent. Pulmonary metastases may occur.

Other primary tumors of the prostate are leiomyoma, fibroma, and sarcomas such as fibrosarcoma, leiomyosarcoma, and hemangiosarcoma. Canine prostatic leiomyomas and leiomyosarcomas have been associated with stranguria, asymmetrical enlargement of the prostate, and metastasis to various organs. Microscopically, multinucleate and anaplastic smooth muscle cells were apparent but immunohistochemistry was used to confirm the diagnosis.

Secondary tumors, especially tumors of the lymphoreticular system, are not too uncommon although uncommonly sought. It is sometimes difficult to differentiate lymphomatous infiltration from the common senile infiltration of lymphocytes. Carcinomas of the neck of the bladder may invade the prostate.

Miscellaneous conditions of accessory genital glands

Atrophy of the accessory genital glands occurs following castration, in advanced age, and sometimes with chronic inflammation. The glands become small, dense, and of tough consistency.

In the dog, the atrophic prostate may be reduced to one-half or one-fourth its normal size. The response to androgen deprivation caused by castration is sudden; ultrastructural studies have revealed that within 3 days many prostatic acinar cells were atrophic and contained large lipid droplets. There was, however, concurrent proliferation of basal cells. Microscopically, after castration, acinar and ductal epithelial cells decrease in size, become less differentiated and more basophilic, and within 3 months epithelium is flat, and acinar lumina small or nonexistent. The stroma concurrently becomes more conspicuous, and smooth muscle of the capsule and trabeculae disappears and is replaced by dense fibrous tissue. Senile atrophy occurs normally in dogs over 11 years of age. Atrophy may also result from distemper, diabetes mellitus, and other systemic diseases.

Concretions in the vesicular glands, bulbourethral glands, or prostate are attributed to precipitation of retained secretions or to chronic inflammation. *Corpora amylacea* may be found in the accessory genital glands of domestic animals. In bulls, vesicular concretions are up to 1.5 cm or more in diameter, irregular, friable, rough externally, and distinctly laminated on section. Histologically, the concretions consist of amorphous eosinophilic debris with occasional clumps of enmeshed nuclear material. They are usually found in inflamed vesicular glands and the lining of the concretion cavity varies from normal to pseudostratified. Concretions are composed of organic components, phosphates, carbonates, and spermatozoa – so-called "*semen stones*." Microconcretions are common in the vesicular glands of rams, unassociated with inflammation.

In dogs, the occurrence of prostatic concretions or calculi is extremely rare and such calculi may be confused with urinary calculi. One report of a large (~30 × 20 × 10 mm), laminated prostatic calculus composed of calcium carbonate and struvite associated it causally with reflux of urine. Calculi are normally 1–5 mm in diameter, hard, white, and spherical, and consist of phosphates and carbonates of calcium as well as urates and oxalates. These form around a crystallization point of organic material – mostly desquamated gland epithelium. The presence of calculi seldom appears to elicit clinical signs. Prostatic calculi have also been observed in sheep.

Metaplastic ossification of prostatic stroma occurs in the dog in association with neoplasia and other chronic conditions. Foci of mineralized bone could, on radiographic examination, be mistaken for calculi.

Intraductal foreign (plant) material has been observed in the bulbourethral gland of the bull associated with chronic adenitis.

PENIS AND PREPUCE

It is convenient and logical for the pathologist to consider these together. There are a number of developmental penile and preputial abnormalities that are of surgical importance but which do not require the contributions of the pathologist; those which do, tend to involve both the penis and prepuce.

Congenital lymphedema in Hereford calves, involving the prepuce, limbs, and tail, is associated with aplasia of lymphatic vessels and nodes. *Penile and preputial hypoplasias* occur mainly as a result of early castration or in intersex states associated with other defects of the urogenital system. In the male cat, the presence of *penile spines* is an indicator of the presence of testicular tissue. A case of *diphallia* or duplication of the glans penis in the cat is described, but as in the ram it was associated with other abnormalities indicative of an intersex state. *Partial or complete lack of the sigmoid flexure of the penis* has been observed in rams and bulls. In the bull, a form of hypoplasia described as *congenital short penis*, possibly associated with shortening of the retractor penis muscle, has been described. Clinical studies on adult bulls with short penis, which would appear to relate also to gross necropsy findings, revealed penile protrusion (penile tip to preputial orifice) of 10–22 cm as opposed to 25–42 cm in normal matched controls. *Hypoplasia of the glans penis* only has been reported. Other rare anomalies in the bull include abnormal insertion of the retractor penis muscle, with stretching of the skin cranial to the testis during erection, partial or complete duplication of the penis, supernumerary ectopic penis, and detached urethral process in which the free end of the penis has a bifid appearance resembling diphallia. Congenital dilation of the penile urethra has been described in the goat. Directional deviations of the erect penis may be attributed to congenital curvature of the os penis in the dog, to asymmetrical development of the corpus cavernosum penis in the horse and donkey, and to *persistence of the penile frenulum* in the bull, buck, boar, dog, and cat (Fig. 5.60), or malfunction of the apical ligament in the ram and bull. Caution is needed in differentiating true persistent frenulum from the balanopreputial fold in normal immature males. Although studies in the boar have indicated some breed susceptibility for persistent

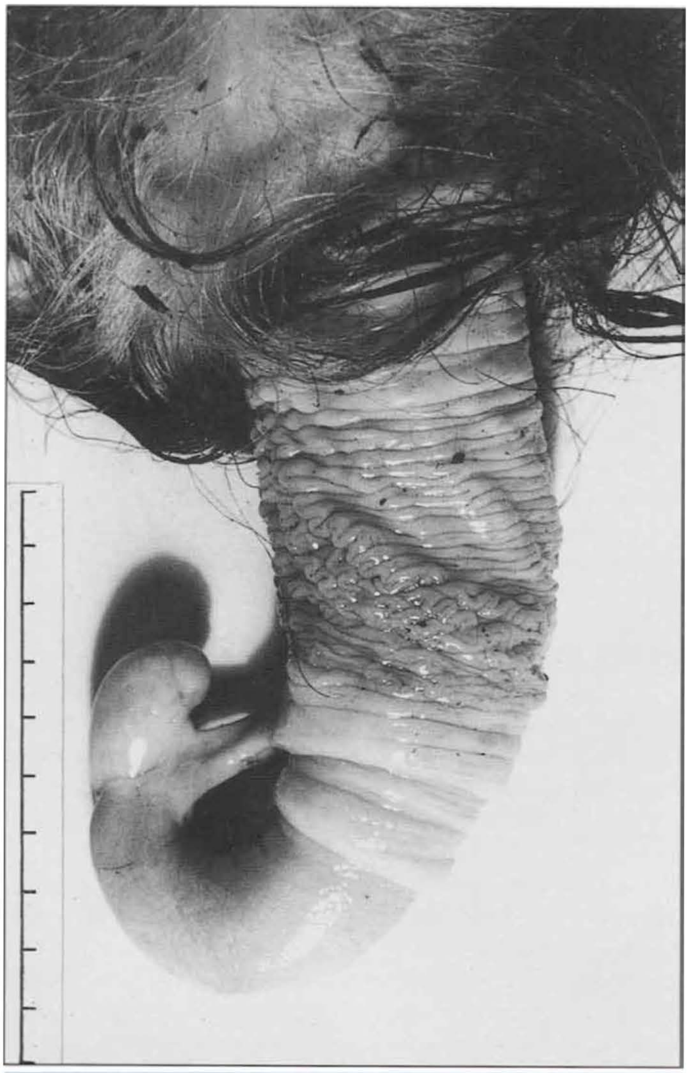

Figure 5.60 Persistent penile frenulum causing ventral deviation of the penis in a bull.

frenulum, there appears to be no definite evidence for inheritance of this trait in any domestic species.

Erection of the penis requires participation of the local circulatory apparatus. Contraction of the ischiocavernosus muscles allows arterial input to the corpus cavernosum and spongiosum, but occludes venous drainage. Abnormalities in vascular function may lead to hemorrhage from the corpus spongiosum to the urethra. Forced deviation of an erect penis may exaggerate the vascular pressures and the structural tensions of the penis. Several important vascular defects of the penis that cause failure of erection, and impotence have been studied extensively in the bull and boar, but their precise diagnosis is not possible at necropsy unless prior study of abnormal angioarchitecture of the penis has been achieved by radiography or injection of plastic into vessels to form casts. These defects in the bull include *rupture of the corpus cavernosum penis* with subsequent hematoma formation, mostly at the distal bend of the sigmoid flexure (Fig. 5.61) but sometimes proximal to it, and *vascular shunts* from the corpus cavernosum to the corpus spongiosum of the penis or to peripenile vasculature which prevent effective erection. *Penile hematoma* resulting from forced deviation of the penis is seen in rams and bulls. Rupture of the corpus cavernosum has also been observed in the stallion, but in this species hemorrhage from vessels outside an intact tunica albuginea is considered more frequent; trauma is the likely cause. Whereas in the bull these defects seem mostly to have an acquired origin, shunts in the boar from the corpus cavernosum penis to neighboring veins appear to be developmental in origin and may be inherited. Immunohistochemical studies of impotence in the boar have provided some evidence that a contributing defect may be defective enervation with depletion of vasointestinal polypeptide (VIP) reactivity in penile nerves. Stallions may develop *varices* of the penile periurethral veins.

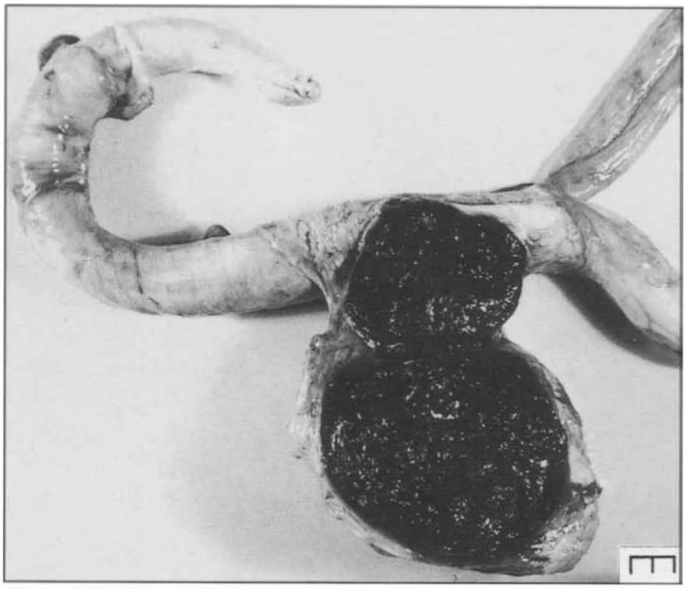

Figure 5.61 Forced deviation of the penis resulted in rupture of tunica albuginea and **hematoma** at the point of attachment of retractor penis muscle at the sigmoid flexure in a bull.

Surgical conditions of the prepuce include *varicosities* of preputial veins in stallions that may lead to thrombosis, edema, and inflammation. In dogs, *trauma to the corpus cavernosum or root of the penis* may occur during attempted copulation and is associated with hindquarter pain and/or lameness, dysuria, and perirenal edema but no obvious hematomas. Extensive *thrombosis* of the corpus cavernosum penis was noted in cats and stallions with a history of priapism of 1–3 weeks' duration, and it was unclear whether the thrombi were the cause or result of pain and persistent erection; in separate stallions, concurrent nematodiasis and generalized malignant melanoma, perhaps with metastases exerting pressure on the pudendal nerve, were, however, considered the primary cause. *Eversion of the preputial mucosa* as a temporary event is common in bulls of the *Bos indicus* species and does occur in polled breeds of *Bos taurus*. The eversion is permitted by inadequate muscular arrangements in the prepuce, and its importance lies in the injuries to which the everted epithelium is exposed. Trauma and desiccation lead to edema and inflammatory change (Fig. 5.62). A *preputial diverticulum* is anatomically normal in the boar but abnormal in the bull and buffalo. Deflection of the penis into the diverticulum results in accumulation of debris, urine, and semen that predispose to local infection and inflammation.

Tearing of preputial mucosa, typically at the ventral preputial fornix, is a common injury that occurs in bulls used for artificial insemination. The precise cause is unknown.

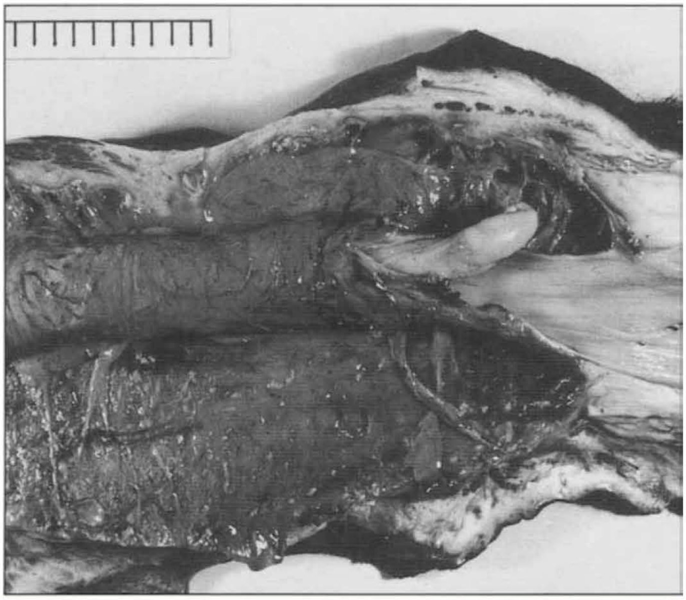

Figure 5.62 Gangrene of the prepuce and peripenile tissues in a bull with preputial prolapse.

Paraphimosis, or inability to retract the penis, is a particular problem in the stallion. Trauma is the most common cause, but inflammation of other causes, neoplasia, or primary penile paralysis may be involved. *Penile paralysis* occurs in severely debilitated stallions, after administration of certain phenothiazine derivative tranquilizers, or as a result of local neurologic disorders.

In the dog, *fracture of the os penis* with resultant callus formation may lead to obstruction of the urethra. Mineralization and ossification of the penis caudal to the os penis is a frequent (usually radiographic) finding and its prevalence increases with age. Urethral obstruction with hydronephrosis and bladder rupture due to aberrant localization of *Ancylostoma caninum* in the caudal os penis has been described.

Inflammation of the penis and prepuce (balanoposthitis)

Inflammation of the glans penis (*balanitis*) is frequently accompanied by inflammation of the prepuce (*posthitis*). Fundamental to an understanding of the causes and pathogenesis of balanoposthitis is an appreciation of the large variety and number of organisms resident in the preputial cavity, and of the existence of local immunity in this location. Viruses such as *Bovine parainfluenza virus 3* in bulls and herpesviruses in many species, nonpathogenic and potentially pathogenic bacteria such as *Corynebacterium renale* and *Histophilus somni*, fungi, mycoplasmas and ureaplasmas, chlamydia, and protozoa are readily isolated from preputial cavities that are normal on clinical and pathological examination. Studies on *Mycoplasma* species and *Ureaplasma diversum* in bulls suggest that the prepuce and distal urethra are areas these organisms mostly colonize.

Reports on whether these organisms cause lesions in the prepuce are conflicting. Lymphoplasmacytic infiltrations of the preputial mucosa, and sometimes distinct lymphoid follicles, probably are responses to the presence of these organisms, but these histologic changes are sufficiently frequent to be considered normal. Immunoglobulins are present in preputial washings, and it seems logical that these are derived from plasma cells of the prepuce. In the bull, the prevalence of these plasma cells tends to increase with age. Possibly, small (T) lymphocytes, frequently seen in preputial and penile epithelium, participate in cell-mediated immune reactions at the epithelial surface. Mucous glands are absent from the epithelium of the penis and prepuce, thus limiting the analogies that can be drawn with inflammatory processes on mucous membranes.

Balanoposthitis in the bull can be caused by ***Bovine herpesvirus 1***. This virus causes both respiratory disease (infectious bovine rhinotracheitis, IBR) and genital disease (infectious pustular vulvovaginitis, IPV). The genital disease in the bull is characterized clinically by thin purulent preputial discharge. Simultaneous occurrence of the respiratory and genital forms of the disease is rare. In the acute stage of balanoposthitis, 2–3 days postinfection, numerous small gray-white opaque foci of necrosis are present (Fig. 5.63A, B). These areas of necrosis may form confluent and flat efflorescences. In severe cases, edematous swelling of the penis and prepuce may occur at this time.

The foci of necrotic mucosa, which exist for 1–2 days only, subsequently become indistinct, the surface sloughs and sharp ulcers or erosions remain, especially in the area of the glans. A distinct zone of hyperemia surrounds many ulcers. Healing commences after 6–8 days and in uncomplicated cases is complete in 2 weeks. For a variable period thereafter, however, lymphoid follicles are present as pale to dark red nodules, arranged separately or in clusters, and seromucoid exudate is present.

The microscopic lesion is one of epithelial necrosis with neutrophilic accumulation, lymphocytic infiltration of surrounding stroma, and the transient appearance of intranuclear inclusion bodies in degenerating epithelial cells. The residual changes are nonspecific. As with other herpesvirus infections, latency occurs and viral production can be reactivated by natural mechanisms or in response to corticosteroids. Although orchitis has been observed in bulls in association with this herpetic infection, it is exceptional.

Herpesviral infection of male goats may also cause similar lesions that may, however, progress to extensive suppurative and necrotizing balanoposthitis involving the glans, fornix, and entire urethral process.

The lesions and pathogenesis of **equine coital exanthema**, caused by *Equid herpesvirus 3*, are in many respects comparable to those of infectious bovine rhinotracheitis in cattle, although the penile and preputial pustules and subsequent ulcers are somewhat larger, being up to about 15 mm in diameter (Fig. 5.64). Lesions in the stallion tend to involve the body of the penis more frequently than the glans. They first appear 2–5 days postinfection as "watery blisters" but rapidly progress to circumscribed yellow pustules with raised borders and depressed centers. Resolution usually occurs within a few weeks leaving depigmented spots, but it is unclear whether the virus remains in the penis and prepuce in a latent form.

In dogs, the genital lesions of ***Canid herpesvirus 1*** infection consist of hyperemia, petechial hemorrhages, and the development of lymphoid nodules, especially over the base of the penis and the preputial reflection. There is an associated serous discharge from the preputial orifice. Lesions appear about 3 days after experimental infection, but are self-limiting, and regress 4–5 days subsequently, with no apparent sequelae. Simultaneous conjunctivitis may sometimes occur. Recurrence of lesions, an important feature of the disease in bitches, seems to be less common in the male. Pustule formation and ulceration do not appear to be a feature of genital herpesvirus infection in

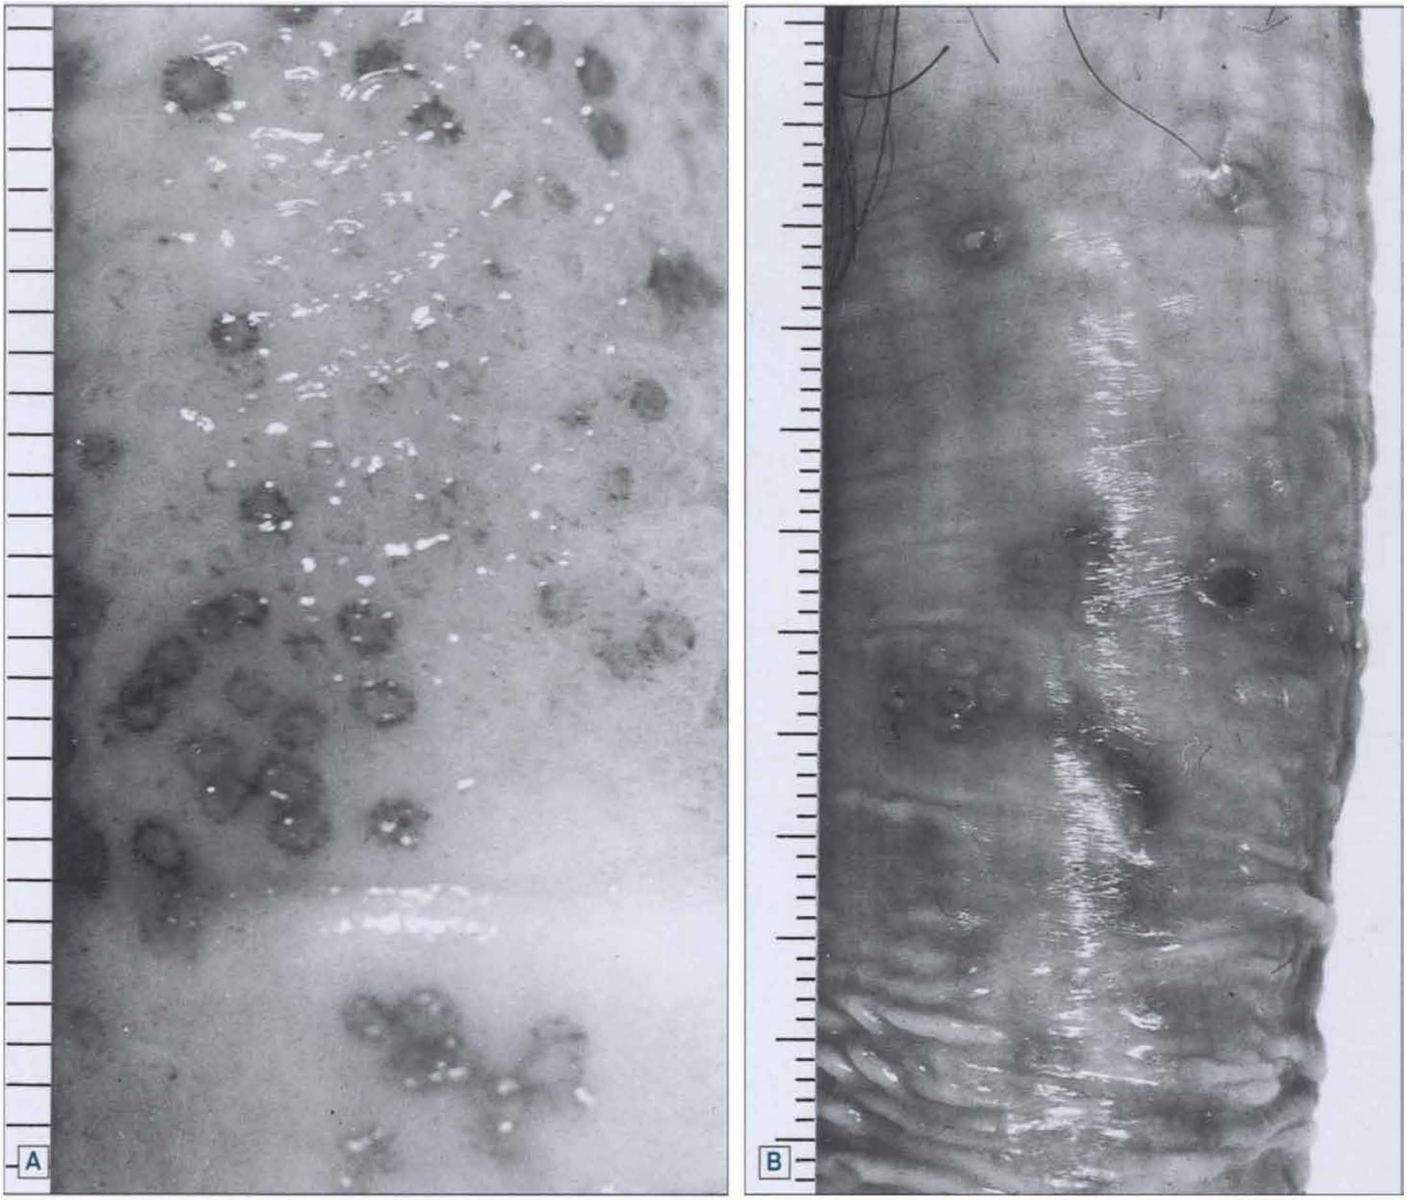

Figure 5.63 *Bovine herpesvirus 1* (BoHV, IBRV) infection producing **multifocal ulcers** on the penis. **A.** Earlier stages have distinct zones of hyperemia. **B.** Later on, ulceration of epithelium occurs.

the male dog even though virus can be isolated from the penis of infected dogs following immunosuppression with prednisolone.

A mild but *chronic balanoposthitis*, not associated with herpesvirus infection and presumed to be bacterial in origin, is common in dogs. Depending upon duration, there is intense hyperemia of the epithelium, mucopurulent exudates, and sometimes ulceration. Lymphoid follicles become enlarged and prominent. Hemolytic strains of *Escherichia coli* are most frequently isolated from such cases, other common isolates being *Proteus vulgaris* and hemolytic streptococci.

Multiple pale dome-shaped papules up to ~3 mm in diameter on hairless parts of the equine prepuce, and on the muzzle, may result from infection with the *Molluscum contagiosum virus* (for details see Vol. 1, Skin and appendages). Histologically, discrete epithelial proliferations with characteristic "molluscum bodies" are present.

In sheep, **ulcerative posthitis of wethers** particularly, but also of rams, is common and important. Vulvitis may occur in ewes in affected flocks. Differences in susceptibility between wethers and rams are probably attributable to incomplete development of the prepuce and penis in the former, and the tendency of the wether to urinate within its sheath.

Development of the primary lesion depends on the occurrence of a transmissible, urea-hydrolyzing bacterium, considered to be *Corynebacterium renale*, and on the excretion of urine rich in urea. In one outbreak, *Rhodococcus equi* and *Corynebacterium hofmanni*, both of which also produce urease, were isolated from lesions. Other factors in urine, possibly hormonal in origin, may also be involved. High protein and especially leguminous diets predispose to the disease and the incidence is lowest during the summer. It is presumed that wethers are infected by the transmission of material on contaminated bedding, herbage, or by flies. Venereal transmission from rams to ewes also occurs.

The lesion in wethers begins as a small yellow area of epidermal necrosis, usually on the dorsal part of the bare tip of the prepuce. This area ulcerates, and slow expansion of the lesion may result in

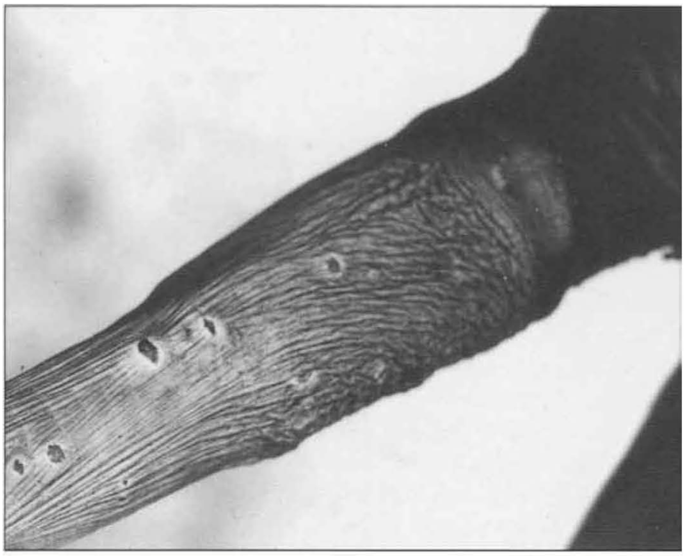

Figure 5.64 Healing ulcers of penis due to *Equid herpesvirus 3* (**coital exanthema**).

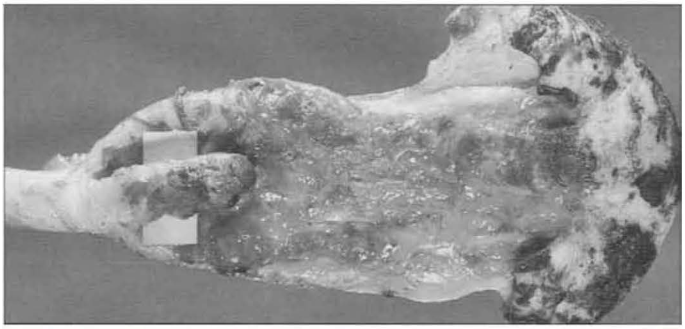

Figure 5.65 Ulcerative **posthitis and balanitis** in a wether. (Courtesy of WJ Hartley.)

occlusion of the preputial orifice. Secondary lesions occur when the prepuce becomes swollen due to the accumulation of urine or pus. At this stage, there is more or less extensive internal ulceration of the prepuce that may slough, destruction of the urethral process, and ulceration of the glans penis (Fig. 5.65). The common name, "*sheath rot,*" describes the condition as this stage. Secondary lesions are uncommon in rams.

A severe **ulcerative balanitis**, distinct from the above condition, occurs in border Leicester rams, in association with vulvovaginitis in ewes mated to them. Morbidity rate can be quite high. Acute deep ulcerations up to several centimeters in diameter occur on the ventral surface of the penis. Excessive granulation tissue and varying hemorrhage become apparent in ulcerated areas and the lesion may extend well above the surface of the penis. Much necrotic and purulent material covers the glans and urethral process, which is markedly thickened. Adhesions of the penis and prepuce may result. Ewes in contact with affected rams have shallow ulcers on the ventral commissure of the labia and posterior vagina. The causative agent has not been identified and it is not clear why border Leicester rams are predisposed.

Traumatic injury by the cocklebur (*Xanthium strumarium*) may cause outbreaks of severe "acroposthitis" in rams with subsequent suppurative vaginitis in ewes mated to them.

Outbreaks of **ulcerative posthitis in bulls** occur occasionally, but these are less severe than in sheep and it is unclear how closely the cause and pathogenesis of this condition parallels ovine posthitis. *Corynebacterium renale*, an inhabitant of the prepuce of apparently healthy bulls, frequently can be isolated from bulls with ulcerative posthitis, and as animals on a high plane of nutrition are predisposed, a parallel of this condition with ovine posthitis is suggested. However, it is not clear why steers are infrequently affected. Mild to severe erosions and ulcerations with associated edema are confined to the preputial orifice and anterior ventral area of the prepuce. Lesions begin as small raised areas of necrosis that are easily dislodged to leave shallow erosions. The ulcers that subsequently develop in these locations are irregular in shape, may be several centimeters in diameter, are sharply defined and frequently bleed. The histological appearance of lesions is nonspecific, with superficial necrosis, reactive epithelial hyperplasia, underlying granulation tissue, and a mixed cellular infiltration. Causal organisms cannot be demonstrated histologically in early lesions, preceding ulceration. In more severe forms of this condition there is increasing edema, abscessation, and myiasis. Deformity of the preputial orifice and phimosis may occur following healing of ulcers.

In bulls, the larvae of *Strongyloides papillosus* may cause severe balanoposthitis. Traumatic injury with subsequent infection by such organisms as *Arcanobacterium pyogenes*, *Escherichia coli*, streptococci, and staphylococci is also common in bulls. Tuberculous balanoposthitis, with characteristic granulomas involving the penis or prepuce, is seen occasionally in bulls from infected herds, sometimes as the only lesion. Genital transmission is possible. The presence of *Campylobacter fetus* subsp. *venerealis* in the preputial sac is not associated with gross or histological changes, although the recognized higher susceptibility of older bulls has been associated with an increase in size and number of crypts in the epithelium of the penis. It seems unlikely that *Campylobacter* spp. can colonize the preputial cavity of male goats; three species (*C. fetus subsp. venerealis, C. fetus subsp. fetus, and C. jejuni*) did not persist following experimental intrapreputial inoculation.

Specific lesions do not accompany preputial infection in bulls by *Tritrichomonas foetus*. Microscopic examination of infected penile and preputial epithelium may reveal cells and debris in crypts, and a slight but mixed cellular infiltrate. Rarely can trichomonads be demonstrated in histological sections. Recognition of the carrier state in bulls in the absence of lesions in both campylobacteriosis (see above) and trichomoniasis emphasizes the need for diagnosis by culture or molecular techniques such as PCR.

Proliferative lesions of the penis and prepuce occur in dogs with **leishmaniasis**, and may be misdiagnosed as transmissible venereal tumor. The lesions, which develop over a period of several months, are apparent as multiple ulcerated nodules up to about 1 cm in diameter located on the penile tip and glabrous preputial epithelium, as well as other organs. Histologically, there is a predominance of macrophages that contain amastigotes of *Leishmania infantum*. Immunohistochemistry is helpful in confirming the diagnosis.

Balanoposthitis is an uncommon lesion in the **stallion** but occurs in dourine, caused by *Trypanosoma equiperdum* (see also Vol. 3, Female genital system) and in cutaneous habronemiasis. Nodular lesions in the preputial lamina of the stallion may also be caused by adults, larvae, and ova of *Halicephalobus* (*Micronema*) sp., or by mycotic infection, particularly pythiosis. Primary infection in **dourine** occurs in the genitalia, following transmission by coitus. There is marked edema of the prepuce and adjacent areas, and phimosis may result. In many cases, yellow-red nodules up to ~8 mm in diameter may subsequently appear on the penis especially near the urethral orifice. These later transform to shallow ulcers, which after healing may leave distinct nonpigmented foci on the skin of the penis, prepuce, scrotum, and perineum. In **cutaneous habronemiasis** (for detailed discussion see Vol. 1, Skin and appendages) also known as "genital bursatti" and "summer sores," the verminous lesions may also be present on other parts of the body. The lesions may affect the penis only, may be around the urethral meatus, or may at the same time involve the preputial mucosa at about the point of its contact with the end of the retracted penis. The lesions are elevated, ulcerated, fungating, and very liable to hemorrhage; they consist of exuberant fibrous tissue enclosing few or many larvae of *Habronema* spp. and may be sufficiently large to cause paraphimosis. There is very dense infiltration by eosinophils, and these accumulate as small eosinophilic abscesses about immobilized and dead larvae. They may be discernible with the unaided eye as small yellow foci on the cut surface. The lesion develops during the summer months. *These larvae very often infect squamous cell carcinomas*, and all "summer sore" lesions should be examined with this in mind. *Geldings* develop a nonspecific posthitis with accumulation of smegma and detritus, presumably because of reduced penile extrusion.

Marked and apparently selective infestation of muscles of the penile urethra in **pigs** may occur several months after infection with *Sarcocystis miescheriana* from dogs. Microscopically, there is hyaline degeneration of muscle fibers and marked infiltration of eosinophils with fewer lymphocytes and macrophages.

Preputial diverticulitis occurs in swine, and the characteristic plaques and ulcers occur in the preputial diverticula of 25–40% or more of castrated and entire male pigs. The lesions commence as foci of hyperkeratosis and progress to distinct white-gray plaques 2–4 mm in diameter with obvious para- and dyskeratosis. As a result of central necrosis, sloughing of epithelium, and neutrophilic infiltration, they form discrete yellow-brown ulcers up to ~10 mm in diameter with raised borders (Fig. 5.66A, B). Such lesions may become confluent, and hemorrhage from them is common. Ulceration is seen most often in older pigs. Calculi may be present in the diverticulum. The precise cause of preputial diverticulitis in pigs is unclear, but accumulation and decomposition of urine are considered of primary importance. *Eubacterium suis*, a cause of pyelonephritis and cystitis in sows, may

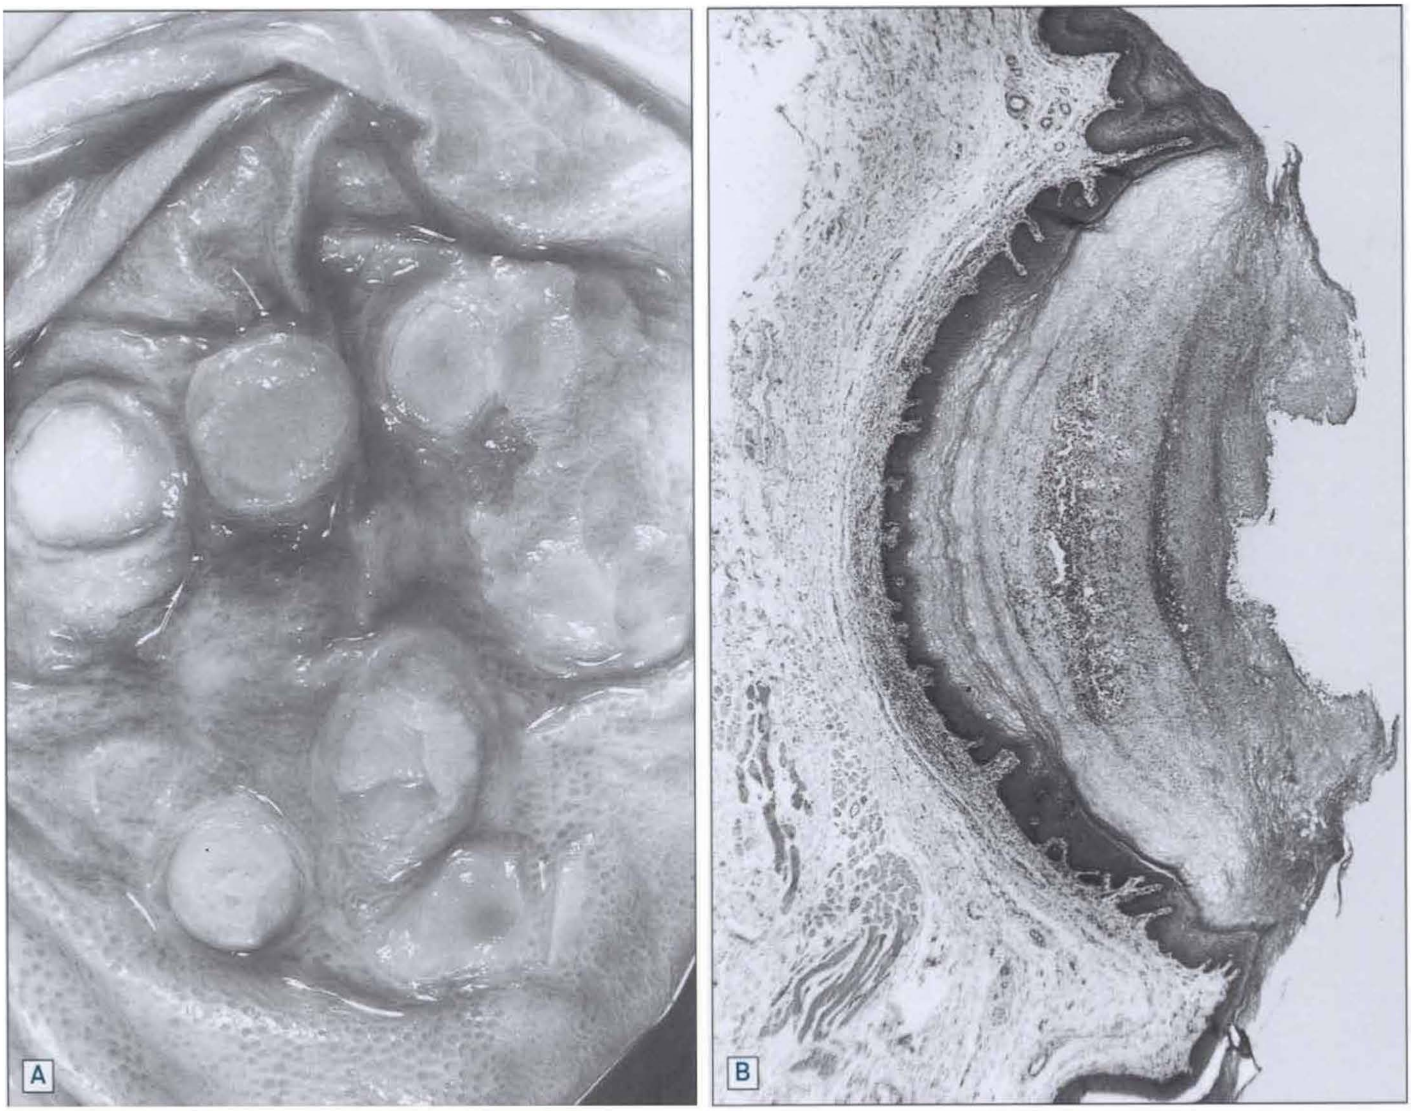

Figure 5.66 A. Plaque and ulcer of the preputial diverticulum in a boar. **B.** Histologic appearance of a plaque in the preputial diverticulum.

be isolated from the prepuce of boars with diverticulitis and healthy boars; the likelihood of venereal transfer exists. Other bacteria frequently present in the diverticulum include *Proteus* spp. and staphylococci. There appears to be no correlation between types of bacteria present and boar performance. An age-related change in bacterial flora of the diverticulum has been demonstrated, *Eubacterium suis* being generally more common in pigs over 4 months of age and in adult boars than in younger animals. Spirochetes also colonize the preputial diverticulum and may contribute to inflammation.

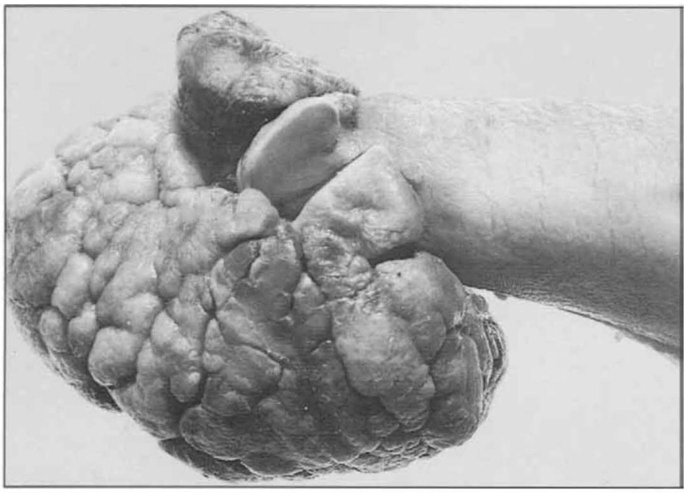

Figure 5.67 Transmissible fibropapilloma in a bull. The exophytic proliferation may be confused with a squamous cell carcinoma.

Miscellaneous conditions causing variable inflammation of the penis and prepuce include *intrapreputial foreign bodies*, and "*hair ring*" in the bull, buck, and cat, in which in-drawn preputial hairs encircle and may constrict the penis.

Neoplasms of the penis and prepuce

The important primary tumors are transmissible fibropapilloma in the bull, squamous papilloma and squamous cell carcinoma in the horse, and transmissible venereal tumor of dogs. Additional details on bovine fibropapillomatosis and canine venereal tumor are given in the Female Genital System.

Fibropapillomas in bulls caused by *Bovine papillomavirus 2* occur on the glans penis. They are most common in young bulls, 1–2 years of age, and may not be noticed until after service, when hemorrhage occurs. They are usually multiple and up to several centimeters in diameter (Fig. 5.67). Tumors are pink or gray-white on section and are composed mainly of fibrous tissue with an epithelial covering of variable thickness (Fig. 5.68A, B). Histologically, there

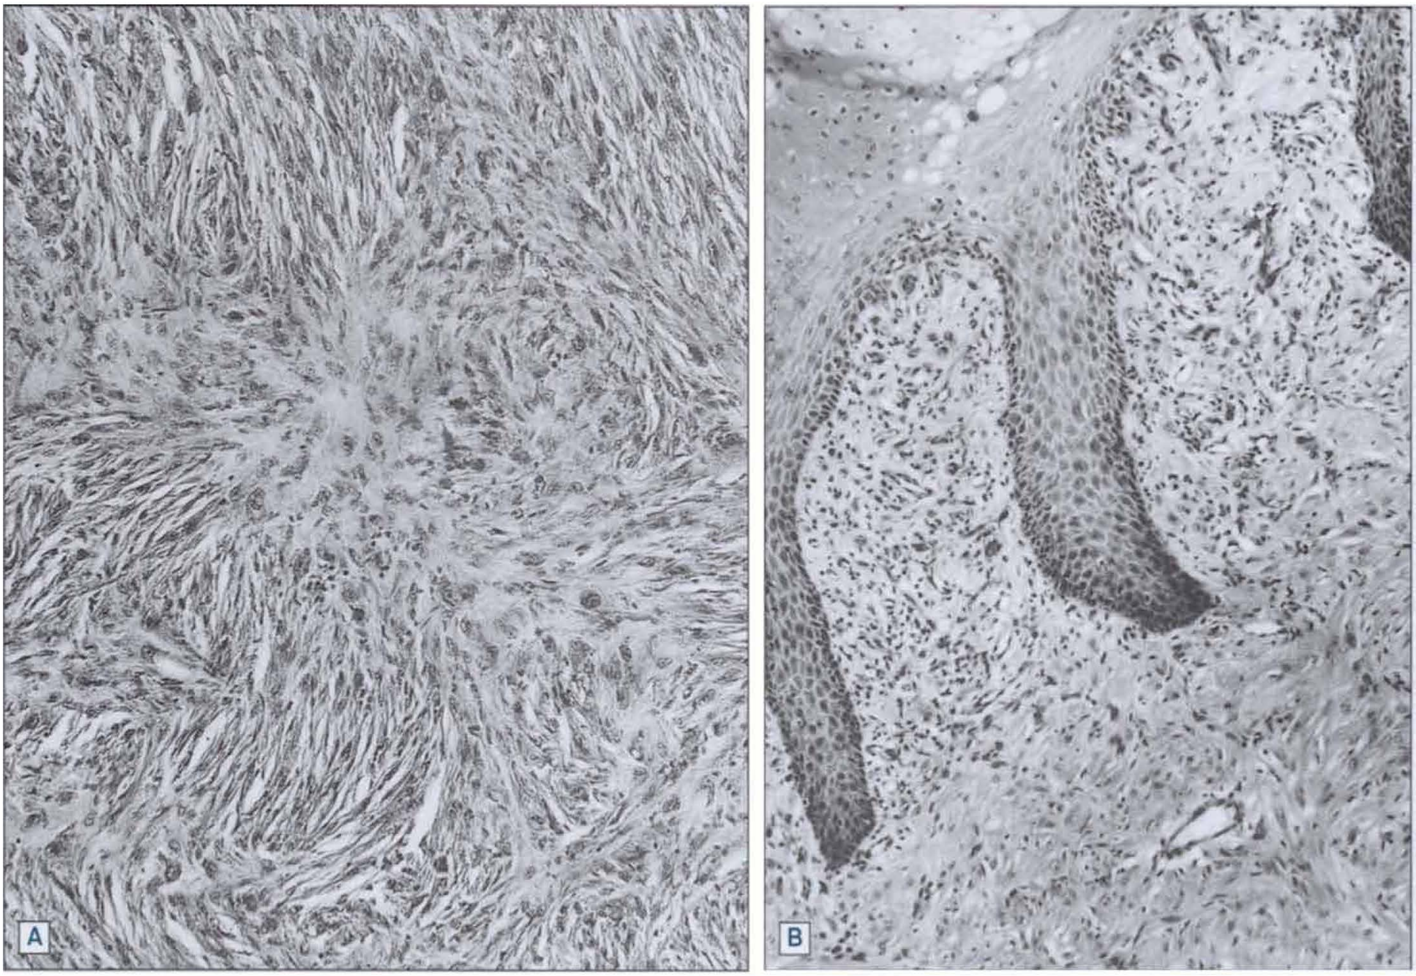

Figure 5.68 Histological details of **transmissible fibropapilloma** in a bull. **A.** Marked fibrous proliferation. **B.** Interface of the connective tissue with the characteristic long projections of epithelium.

are differences between tumors in young and old bulls, those in young bulls being more cellular with frequent mitoses.

Although benign, large fibropapillomas in bulls may interfere with free movement of the penis through the preputial orifice and retraction of the glans may be prevented. In such cases, preputial hairs may engage the prolapsed penis and cause strangulation. Alternatively, continued growth of the mass within the preputial cavity may prevent penile protrusion. The urethra may then be so compressed that rupture occurs and extensive cellulitis results from infiltration of urine in the peripenile tissues.

A *transmissible genital papilloma* has been reported in **swine**. Both the natural and experimental neoplasms regress with time. Papilloma virus antigen is present in the tumor, but the virus has not been recovered. The tumors are small, round, and project 3 cm from the mucosal surface. Histologically, they are characterized by excessive thickening of the stratum spinosum with exaggeration of the rete pegs. There is little proliferation of the underlying connective tissue. A thin layer of keratinizing cells covers the hyperplastic epithelium.

Squamous papilloma in all species is a benign, keratinizing epithelial papilliform tumor with little fibrous stroma; it is usually small and is frequently associated with lymphoplasmacytic infiltration. Squamous papilloma is most common in the *horse*, however, and is the benign counterpart of squamous cell carcinoma.

Squamous cell carcinoma (SCC) of the penis and prepuce has been described in the horse, dog, and bull, but it is possible the bovine cases were fibropapillomas. In the **horse**, SCCs occur with about equal frequency in stallions and geldings and the average age is greater than 12 years. Because SCCs in the equine penis and prepuce have occurred at sites of prior removal of squamous papilloma, any papilloma in these locations should be considered as premalignant. As with SCC elsewhere, over-expression of p53 seems to be involved in development of this tumor in the equine penis. Tumors arise mostly from the glans. Superficial ulceration and necrosis of large tumors are common (Fig. 5.69). Histologically, the penile tumor is usually well differentiated and keratinization is almost always present. Infiltration of inflammatory cells, especially eosinophils, around the tumor is common, and foci of necrosis and mineralization are frequent. Extension of the tumor occurs either by infiltration into the corpus cavernosum or by metastasis, especially to the inguinal lymph nodes and less frequently to other organs such as lung or liver. In the **dog**, SCC of the penis and prepuce has been associated with papillomavirus. It is of similar appearance to that in the horse but may be non-keratinizing. Approximately 25% of reported cases had metastasized, chiefly to the inguinal lymph nodes.

Transmissible venereal tumors in the male dog mostly arise on the penis or within the prepuce. They may be single or multiple, sessile or pedunculated, nodular or papillary, soft to firm consistency, and up to ~15 cm in diameter (Fig. 5.70). Histologically, the usual pattern is one of solid sheets of uniform round, ovoid, or polyhedral cells with large round vesicular nuclei. Mitoses are common. Metastasis occurs in up to 5% of cases and may involve the superficial inguinal lymph nodes and various organs. Most cutaneous metastases are considered to result from trauma and mechanical implantation. Spontaneous regression of tumors sometimes occurs, and usually they are sensitive to chemotherapy with vincristine. Immunohistochemical staining characteristics suggest they are of histiocytic origin, as they are positive when stained with

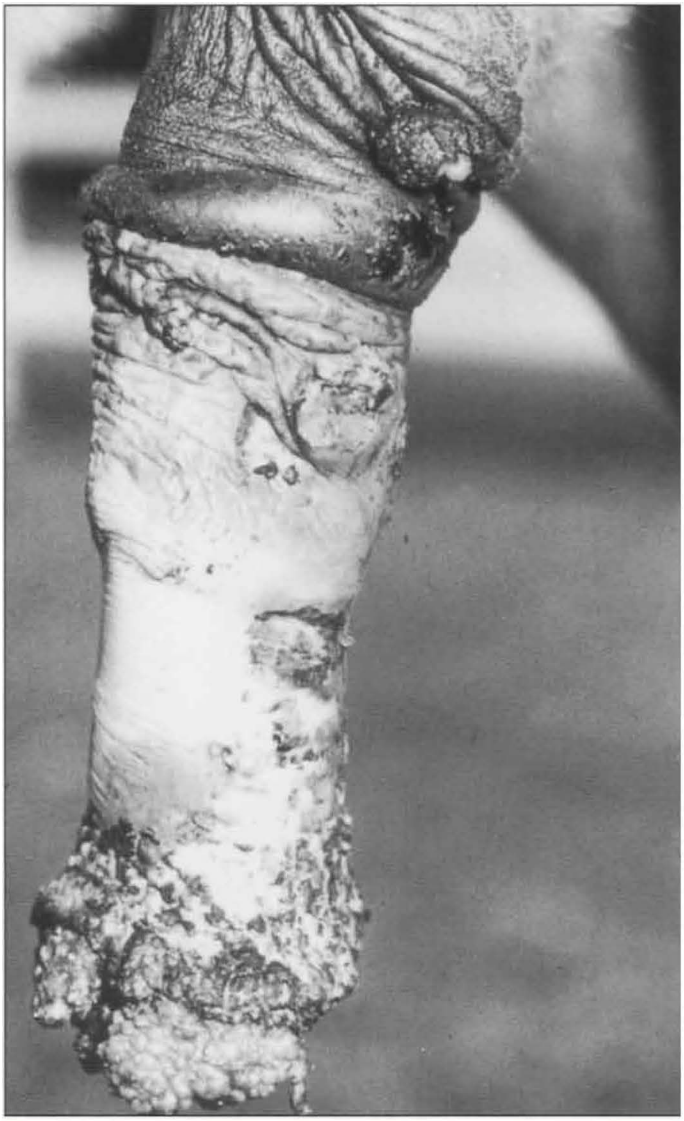

Figure 5.69 Squamous cell carcinoma of the penis of a horse. Squamous cell carcinomas often cause enlargement of the penis, which becomes hard and tough from the desmoplastic response to the neoplastic cells. (Courtesy of KG Johnston.)

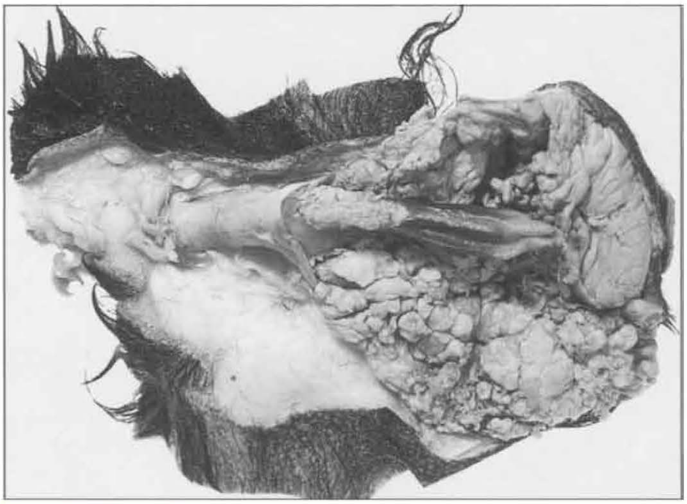

Figure 5.70 Transmissible venereal tumor on the penis and within the prepuce in a dog.

vimentin, often positive with α1-antitrypsin and lysozyme, and negative for CD3, immunoglobulins, and cytokeratin (for more detail see Female genital system).

Less common tumors of the penis or prepuce include apocrine sweat gland adenocarcinoma of the equine prepuce, mast cell tumor, malignant melanoma, hemangiosarcoma, lymphosarcoma in which cell infiltration may be either diffuse or nodular, osteosarcoma, chondrosarcoma, and ossifying fibroma of the os penis in a dog.
